WASHINGTON : 1934

Organization of the United States Department of Agriculture

Corrected to April 15, 1934

Secretary of Agriculture.....	HENRY A. WALLACE.
Assistant Secretary.....	REXFORD G. TUGWELL.
Director of Scientific Work.....	A. F. WOODS.
Director of Extension Work.....	C. W. WARBURTON.
Director of Personnel and Business Administration.....	W. W. STOCKBERGER.
Director of Information.....	M. S. EISENHOWER.
Solicitor.....	SETH THOMAS.
Agricultural Adjustment Administration.....	CHESTER C. DAVIS, Administrator.
Bureau of Agricultural Economics.....	NILS A. OLSEN, Chief.
Bureau of Agricultural Engineering.....	S. H. MCCRORY, Chief.
Bureau of Animal Industry.....	JOHN R. MOHLER, Chief.
Bureau of Biological Survey.....	JAY N. DARLING, Chief.
Bureau of Chemistry and Soils.....	H. G. KNIGHT, Chief.
Office of Cooperative Extension Work.....	C. B. SMITH, Chief.
Bureau of Dairy Industry.....	O. E. REED, Chief.
Bureau of Entomology.....	LEE A. STRONG, Chief.
Office of Experiment Stations.....	JAMES T. JARDINE, Chief.
Food and Drug Administration.....	WALTER G. CAMPBELL, Chief.
Forest Service.....	FERDINAND A. SILCOX, Chief.
Grain Futures Administration.....	J. W. T. DUVEL, Chief.
Bureau of Home Economics.....	LOUISE STANLEY, Chief.
Library.....	CLARIBEL R. BARNETT, Librarian.
Bureau of Plant Industry.....	KNOWLES A. RYERSON, Chief.
Bureau of Plant Quarantine.....	A. S. HOYT, Acting Chief.
Bureau of Public Roads.....	THOMAS H. MACDONALD, Chief.
Weather Bureau.....	WILLIS R. GREGG, Chief.

FOREWORD

FROM its start the United States Department of Agriculture has promoted efficiency on the farm. Efficiency in the old sense of the word, however, is not enough. As farmers well know, profits cannot be got just by improving plants and livestock, by fighting diseases and pests, or by reducing the wastes of marketing. That alone is not efficient. Ordinary technical efficiency reduces only the cost of production; under present conditions it is necessary also to adjust the output to a changed world market. Low-cost production may mean loss to the farmer if it is excessive production. ¶In this Yearbook the Department reports what it has done recently toward adjusting production and promoting efficiency. The annual report of the Secretary to the President, with which the volume opens, tells about action taken under the Agricultural Adjustment Act of 1933. This legislation enables the farmers, with Federal guidance, to plan their production. It seeks to transform blind competition into broad-visioned cooperation, and to correct the result of previous mistakes. Under the heading "What's New in Agriculture", the Yearbook contains articles by Department specialists recounting progress in research, in law administration, and in practical service to agriculture and to the Nation. In short, the volume reports things done both in economic adjustment and in technical research. ¶These two kinds of departmental activity do not conflict but go together. Economic adjustment and technical research are necessary mutual supports, particularly just now. Even in normal circumstances it is difficult to prevent a clash between technical efficiency and profitableness in farming. As more and more farmers adopt the latest methods, their aggregate production increases until prices fall below costs. In periods of great overproduction, increased efficiency is a very mixed blessing, if farmers do not counteract its tendency to swamp the market. They cannot do so profitably by ceasing to be efficient. Such a course would increase costs more than it would increase prices, and would give an advantage to competing countries. The only workable expedient is economic adjustment. ¶Agriculture needs not less science in its production, but more science in its economic life. We may usefully distinguish between productivity and production. Real efficiency increases the former but not necessarily the latter. Farmers cannot have too much productivity or production power, provided they keep it under control. High productivity means low unit costs. With efficient economic as well as efficient technical practice, farmers can make productivity their servant. It is half-science that turns research into a Frankenstein, and leads to demands for a halt in technical progress. Full science embracing the distribution as well as the production of wealth reconciles the conflict. ¶In the last year our farmers have taken their first steps toward matching efficiency in production with efficiency in economic adjustment. As they proceed along this path, they will realize that the more they have of the one type of efficiency the easier they will find it to achieve the other. The reason is plain. Efficient production is more dependable, and therefore more easily controlled, than inefficient production. By considering economic and technical problems equally, and by indicating their interdependence, this Yearbook emphasizes a principle destined, I believe, to become vitally important.

HENRY A. WALLACE, *Secretary of Agriculture.*

THE YEAR IN AGRICULTURE

The
SECRETARY'S REPORT
TO THE PRESIDENT

WASHINGTON, D.C., *November 15, 1933.*

To the PRESIDENT:

THE DILEMMA OF THE SURPLUSES

In the simpler days before the war when we were a debtor Nation and foreign nations were willing to take all we could produce in satisfaction of our debt, we were not bothered by thoughts of economic planning. Production overshot demand only occasionally and temporarily. Foreign nations wanted our goods and had the means to pay for them.

The war and its consequences changed the situation utterly. With our production power vastly expanded and the foreign demand greatly curtailed, it was necessary to establish a new balance. This required adjustments in both supply and demand. Agriculture, especially, found itself in a dilemma. It could not reduce its output as rapidly as the demand declined and there was no way to increase the demand. It was involved in heavy production for a foreign market that had been forced, for lack of purchasing power, to cease, or almost to cease, buying. In these circumstances economic planning became not merely advisable but necessary. Adjusted production on the one hand and restored buying power at home and abroad on the other stood out as things absolutely indispensable to agricultural recovery.

Accordingly, the farmers of the United States are beginning to plan together under Federal guidance. Agricultural conditions have improved greatly during the last 6 months, partly because something has been done to balance production with demand and partly because Government action has improved the economic situation generally. Rising farm prices and farm incomes and the return of hope and confidence to the agricultural community are matters on which one is tempted to dwell. But it is more important to emphasize the problems that await solution.

The recent improvement is not simply a typical phase of the economic cycle or a natural turning of the tide, but a result, in large part, of deliberate policy and action. It by no means signifies that customary ways of doing things may safely be resumed. It is necessary to ponder carefully the conditions out of which the improvement developed, so that we may make it lasting.

Tremendous Price Disparity

What the depression of 1929-33 did to agriculture appears most strikingly in the tremendous disparity it produced between the prices of farm commodities and the prices of the goods that farmers usually buy. Farm-commodity prices had dropped by early 1933 to a point 50 percent below the pre-war level, whereas in 1928 they had averaged nearly 50 percent above. Prices paid by farmers for commodities dropped down to, but not below, the pre-war level. Thus farm commodities had only half their pre-war unit-purchasing power. Gross farm income from the production of 1932 was less than half that of 1929, whereas fixed charges, including taxes and interest, were not proportionately lower. Mortgage interest and taxes together took almost 25 percent of the gross farm income. As a result of the big drop in farm prices and the comparatively small declines in farm costs, the average farmer after paying the expenses of production, interest, rent, and taxes had only about \$230 left. This gave him nothing as a return on his investment and much less than common-labor pay for his labor and management.

Agriculture, in short, was very sick, and the disease from which it suffered threatened also the entire community. Ruinously low farm earnings tended to separate farm operation from farm ownership and to degrade farmers into virtual serfdom. The collapse of farm prices caused a heavy loss in farm valuations, in which farmers' equities were destroyed. All the capital employed in agriculture had a value in January 1933 of only \$38,000,000,000, as compared with \$58,000,000,000 in January 1929 and \$79,000,000,000 in January 1919. Farmers bore the brunt of this terrific decline, because farm debt remained virtually unchanged. Average mortgage debt per acre was nearly three times greater than in the pre-war years.

Farm land values had fallen, for the country as a whole, to about three fourths of their pre-war value. Forced sales of farms had risen to new high levels. Agriculture was in fact thoroughly insolvent. Creditors could not collect their claims and became involved themselves. City people could not sell their products to farmers. The stability not merely of agriculture but also of business hung in the balance. Indeed the threat was not merely to urban business but to urban security, for social security in cities cannot long survive its disappearance in the country. The depression robbed farmers of their independence, formerly the chief attraction of country life, and thereby weakened the foundations of our whole economic system. It tended, through foreclosures and bankruptcies, to shift farm ownership from the country to the town, but under conditions that made the shift a peril rather than an advantage to the new owners.

Causes of Farm Distress

This was the situation that confronted agriculture and the Nation when the present administration took office. Some details will throw light on the causes and help to explain the relief program adopted a little later. Under the double stimulus of price and of patriotism, American agriculture during and after the war expanded tremendously its production for export. Our agricultural exports, which had generally fallen from 1898 to 1913, reached a record level in 1919. In that year we exported 15.8 percent of our farm production.

Thereafter the trade declined, gradually until 1929 and then sharply. Since then the export proportion has averaged less than 7 percent of the farm production. There has been no corresponding decline in total output, which on the contrary has increased. Here in a nutshell is much of the explanation for the agricultural depression. Declining exports with mounting production naturally mean mounting surpluses. When export surpluses cannot be profitably sold, domestic sales show a loss too; blocked export outlets force supplies back into the home market and swamp it.

It is true that the depression of 1929 caused a decline in the domestic as well as in the foreign demand for agricultural products. Industrial conditions within the United States affect our agriculture vitally. Factory employment diminished so greatly in 1930, 1931, and 1932 that the purchasing power of the urban community fell by more than half. The decline in industrial activity wiped out the per capita increase in that activity of the previous 30 years. In such circumstances farm products had necessarily to be offered at sacrifice prices. Yet the inevitable loss would unquestionably have been smaller had trade channels not been glutted with unsalable supplies intended for export.

This is evidenced by the fact that farm commodity prices declined far more than other prices. Had farm production not been over-expanded in relation to its total market, an exactly opposite tendency would have developed, because the per capita consumption of farm products declines for obvious reasons much less than that of other goods during depressions. Primarily, therefore, the distress of American agriculture from 1920 to 1929 may be attributed to the existence of unwanted export surpluses and after 1929 also to the weakness of domestic demand. The fact that other industries not similarly overexpanded suffered too indicates that agriculture would not have escaped scot free in any event; but the exceptional degree to which agriculture suffered points clearly to relative over-production as the principal cause.

Position of Some Leading Farm Products

The position of some leading farm products shows the magnitude of the surplus problem. World carry-over of American cotton in the 1932-33 season was 13,000,000 bales—about two and a half times the normal carry-over. Yet world cotton production in 1932-33 was the smallest since 1923-24, with the exception of 1927-28. This country's contribution to the total, though yields were normal, was nearly a fourth less than that of the previous crop year. It is difficult to imagine more impressive evidence of the extent to which the capacity to produce cotton had overshot the demand. Our cotton area increased from 28,678,000 acres in 1921 to 44,616,000 acres in 1926. Above-average yields on a cotton acreage equal to that of recent years would give a production far above the world's average annual consumption of American cotton. Average yields on foreign cotton acreage will produce from 11,000,000 to 12,000,000 bales annually. Cotton acreage in foreign countries is down only slightly from the 1925-26 peak.

Before the war the cotton situation was pretty well balanced. Production was increasing both in the United States and in foreign

countries, but so was the demand. War-time and post-war developments obscured the possibility that this well-balanced position might not last. After a brief post-war slump, cotton prices soared to high levels. Growers responded by increasing their acreage, and by 1925-26 the world had nearly 87,000,000 acres in cotton. Signs then appeared that production had been overdone. World consumption of American cotton fell in 1929-30 to 13,000,000 bales, as compared with 15,000,000 bales or more in each of the 3 preceding years. Cotton consumption fell heavily in the United States. This country, as the world's largest source of cotton, found itself burdened with a crushing surplus.

Equally staggering was the wheat surplus. In the nineteenth century this country had in Europe a market for all the wheat it had to spare. We exported, mostly to Europe, no less than 227,240,000 bushels in 1898. The trade declined in the early years of the twentieth century, and by 1911 the wheat exports had dropped to 81,891,000 bushels. American farmers adjusted themselves to the change, altered their production somewhat, and continued to prosper.

The war threw our wheat industry back into high production for export. By 1920 our wheat exports had risen to 369,313,000 bushels—far above the peak reached in the nineteenth century. Other wheat-exporting countries increased their production and exports. In 1890 the United States produced about eight times as much wheat as the combined production of Canada, Argentina, and Australia. These three countries in 1928-29 produced more wheat than we did. They produced 1,076,000,000 bushels, practically three quarters of which competed with our wheat in the European market. After the war Europe restored its wheat production. It increased the yield from 1,100,000,000 bushels in 1922 to 1,500,000,000 bushels in 1932.

As a result of all these circumstances, we had, after the crisis of 1929, a wheat production far exceeding the market demand. In 7 of the last 8 years the production of wheat in the United States exceeded 800,000,000 bushels; in 2 of those years it exceeded 900,000,000 bushels. From 600,000,000 to 700,000,000 bushels went into domestic consumption. The rest had to be exported or stored. In the existing world-market situation, American net wheat exports declined inevitably. They were less than 32,300,000 bushels in 1932-33, as compared with 142,000,000 bushels in 1928-29. Our wheat carry-over increased to nearly 370,000,000 bushels in 1933, or more than three times the normal. We had on hand in this country almost half a year's average production.

Similar conditions existed in the hog industry, which during the war expanded its exports of hog products by about 200 percent, or the equivalent of 10,000,000 hogs. After the war European countries restored their hog production. Our exports of hog products had trended downward since the war, though lard had not been so much affected as pork. The war-time increase had disappeared. In 1932 the exports represented the equivalent of only 5,000,000 hogs, as compared with more than 16,000,000 in 1919. American hog farmers were beset with an excess-production problem because of a severe contraction in their export outlet, just as were the wheat and cotton growers. There had been no proportionate adjustment in hog production. On the contrary, the hog farmers had continued their production almost as if the large war-time European demand still

existed. On January 1, 1933, the estimated number of hogs on farms in the United States was 60,716,000, as compared with 63,800,000 on January 1, 1919.

These examples, which have their counterpart to a lesser extent in other farm commodities that are exported in substantial amounts, demonstrate positively that the American farm problem is largely a result of a greatly reduced export market. With excessive production for export, adjustment to demand in the home market is impossible. Under that handicap, a complete industrial revival in the United States accompanied by a great increase in consumer buying power would not restore prosperity to the farmers. Export surpluses that cannot be sold become domestic surpluses; and it is a truism that prices cannot rise permanently in overstocked markets.

Our Creditor Status

Overproduction for export is not a temporary difficulty, which will tend to disappear spontaneously with the revival of industry and trade throughout the world. Our large agricultural export trade during and after the war rested on foundations too precarious to be restored. It rested mainly on credits extended by this country to the importing nations. We went into the World War owing other nations 200 million dollars annually on interest account. We came out of it with other nations owing us more than 500 million dollars annually. Other nations now owe us annually on interest account more than 1 billion dollars. They are compelled in consequence to reduce their purchases here, all the more since we do not afford them a market for their products. The struggle of the debtor countries for agricultural self-sufficiency, and their natural inclination to buy where they can sell, make it inconceivable that the foreign demand for American agricultural products will expand sufficiently in the near future to absorb our surpluses.

After the outbreak of the war, our foreign creditors sold American securities freely in the United States, thereby reimporting capital which they had previously exported. In addition, American investors loaned half a billion dollars to the allied nations. After the United States entered the war, the Federal Government made loans to European countries. The total ran to more than 10 billion dollars. This enormous outflow of funds, which continued for a time after the war, provided European nations with a greatly increased purchasing power for American products. As a result, the excess of our exports over our imports became very large. In the peak year, 1919, it amounted to about 4 billion dollars.

In short, the United States faced the necessity of receiving from the debtor countries an increasing quantity of goods and services in payment of their obligations. This result was postponed up to 1930 by further lending. But only by lending indefinitely, in ever-increasing amounts, could this country in the long run avoid importing more than it exported. Such a one-sided movement of capital and of goods cannot be permanent even in an extremely favorable world-trade situation. It is necessarily brief when depression destroys credit. Our excess of exports over imports remained larger on the average between 1924 and 1930 than before the war not only because we loaned much capital to foreign countries but also because American

tourists made large expenditures abroad and because emigrant remittances and ocean freight payments were heavy. The depression weakened all these supports of the export trade.

After the crisis of 1929 American lending to foreign countries diminished greatly. The transfer of funds from the United States to foreign countries did not, however, cease entirely. Though our investors stopped buying foreign bonds in large amounts, foreigners withdrew considerable sums which they had on deposit in American banks. Moreover, Americans transferred large amounts to Europe after the depreciation of the dollar last March. But this outflow of short-term money cannot continue indefinitely. Inevitably, therefore, our trade balance will become less favorable. Only by foreign lending on an increasing scale can the excess of exports over imports be maintained, and the chances are against that development.

Choice of Two Lines of Policy

This Nation consequently faces a choice between two lines of policy—either it must modify its tariff policy so as to permit a larger quantity and value of imports to enter the country, or it must accept a considerable and permanent loss of its foreign markets. A revival of lending, if that were possible, would postpone the necessity for making the choice but would not obviate it permanently. Manifestly the issue is of supreme importance to agriculture, which remains one of our principal exporting industries. It will probably be necessary, in any event, to count on some permanent reduction in the export demand for agricultural products; but how large the necessary reduction will be depends greatly on our tariff policy. We cannot go on selling abroad without buying abroad.

Failure to recognize such fundamental changes in debtor and creditor positions leads to political situations that complicate the supply-and-demand equation. These situations nevertheless do not override the law of supply and demand, which is remorseless in its operation. They may postpone, but cannot avert, the final reckoning. Since March 4 last the country's affairs have improved greatly. There has been a total increase in industrial pay rolls of about 65 percent, and the purchasing power of farm products has advanced materially. This improvement, however, cannot last if we do not meet the problem caused by the fact that we have at least 40 million too many acres of plow land in crops, in view of the international situation on debts, tariffs, and foreign lending.

The United States is a creditor nation with a debtor nation psychology. The American people are still essentially high-tariff in their attitude. They are disillusioned about lending money abroad and yet do not wish to allow foreign nations to send goods here to pay for our wheat and cotton and other exportable commodities. It must be one thing or the other. Either we must modify our tariff policy and perhaps also our policy with regard to international debts and foreign lending, or we must put our internal economy on substantially a nationalist basis. The best course would be to work toward an expansion of foreign purchasing power in definite, tangible ways—through tariff adjustments and eventually through renewed foreign lending accompanied by a willingness to receive certain goods in exchange for the money loaned. The alternative

course, along which we are now moving, answers the need of the emergency but demands superhuman efforts if it is to be permanent. With the foreign market practically lost, keeping down acreage and livestock production to a point that would afford a living price level to the farmers would be extremely difficult. It is necessary to balance our productive forces to the kind of world we want to live in. We have not yet decided what kind of world we want.

Emergency Adjustment Necessary

The world situation being what it is, our immediate task is to accomplish an emergency adjustment of farm production to the demand. This does not mean renouncing foreign trade. It is possible simultaneously to set about adjusting our farm production to the total demand, domestic and foreign, and to work for the removal of unnecessary impediments to international commerce. We normally export more than half our cotton, nearly half our tobacco, a fifth of our wheat, and from a third to a half of our packing-house lard. On the average we exported 13.6 percent of our agricultural products annually during the 10 years 1919-28. It is obvious that foreign trade will continue to be vitally important to American agriculture. Recognition of that fact is perfectly consistent with a determination not to offer our foreign customers vastly more than they can possibly take. If our foreign trade could be revived quickly by negotiating reciprocal tariffs and making intergovernment debt adjustments, the need for readjusting our farm production would be less urgent. It would remain nevertheless, because the production exceeds even the most optimistic estimates of the probable demand. As things now stand in the international sphere, the necessity of beginning with production adjustments is overwhelming.

To sum up the situation, American agriculture before the war stood in a satisfactory relationship to its markets, both foreign and domestic. Agricultural prices rose more than other prices. Net farm earnings increased, and also farm valuations. Farm exports declined after the beginning of the century, but growing consumption at home compensated for the decline. The war drew the United States back into tremendous production for export, while saddling the importing countries with debts and political troubles that reduced their buying power. Temporarily it created shortages of commodities both agricultural and industrial; but agriculture and industry overestimated the shortages and soon replaced them with surpluses. Tariffs excluded foreign goods which this country might have received in payment for its agricultural exports. Loans furnished our foreign customers an undependable means of payment which eventually failed. The crisis of 1929 developed largely as a consequence of these inconsistencies, though monetary difficulties in many countries played a considerable part therein. As their buying power declined, foreign countries adopted trade restrictions which added to our export difficulties, and brought world trade under governmental control to an extent unprecedented in modern times. As a result, the demand for the products of the farm dropped catastrophically, while the production remained virtually unchanged.

AGRICULTURAL ADJUSTMENT LEGISLATION

Congress provided means for dealing with the farm problem in an act (Public No. 10, 73d Congress).

to relieve the existing national economic emergency by increasing agricultural purchasing power, to raise revenue for extraordinary expenses incurred by reason of such emergency, to provide emergency relief with respect to agricultural indebtedness, to provide for the orderly liquidation of joint-stock land banks, and for other purposes.

The act, which was approved by the President on May 12, 1933, has three titles, two applying directly to agriculture, and the third to the national currency.

Title I deals with farm-production control and marketing agreements, and gives the measure its popular name—The Agricultural Adjustment Act. Title II relates to farm credits by amendments to the Federal Farm Loan Act, and by appropriations for various types of agricultural credit. Title III empowers the President to arrange for the expansion of credit by the purchase of Government securities through the Federal Reserve banks, to cause the issuance of United States notes in his discretion up to the amount of \$3,000,000,000, and by proclamation to fix the weight of the gold dollar and the silver dollar. This title is called the Inflation Amendment to the Agricultural Adjustment Act and affects agriculture along with other industries by its potential influence upon the general price level.

In a declaration of policy under title I, the act says it is the purpose of Congress to establish such a balance between the production and the consumption of agricultural commodities as will restore the purchasing power of farm products "to the level of the base period." For all agricultural commodities except tobacco, the base period is the pre-war period August 1909 to July 1914. For tobacco the base period is the post-war period August 1919 to July 1929. To protect consumers, the act declares that farm production must be adjusted so as not to give the farmer a higher percentage of the consumer's total retail expenditures for agricultural commodities than he received in the base period.

Crop Adjustments and Marketing Agreements

The measure seeks to raise the incomes of farmers by two principal means: (1) By getting their cooperation in necessary crop adjustments calculated to bring supply into a better balance with demand; and (2) by authorizing the Secretary of Agriculture to enter into marketing agreements with producers, processors, and distributors of agricultural products, so that competitive wastes may be eliminated, trade practices improved, surpluses moved into markets for consumption, and producers' prices raised.

In connection with certain basic agricultural commodities, the Secretary of Agriculture may make compensatory payments to producers in return for agreements to curtail their acreage or their production for the market. The basic commodities specified are: Wheat, cotton, corn, hogs, tobacco, rice, and milk and its products. It is not mandatory for the Secretary to take this action.

He may levy taxes on the first domestic processing of any of the basic commodities, in order to raise funds for the necessary payments

to farmers. The act also appropriates \$100,000,000 under title I for administrative expenses and compensatory payments, and authorizes the Secretary of the Treasury to advance funds to the Secretary of Agriculture in anticipation of the proceeds of processing taxes.

Under the sections relating to marketing agreements, the Secretary of Agriculture may bring producers, processors, or handlers of farm commodities into trade relationships calculated to promote a better adjustment of supply to demand, to assure fair prices to producers, and to protect the consumer. He may license the parties concerned under regulations penalizing violations of the agreements. The antitrust laws do not apply to agreements thus made.

Farm Debt Sections of the Act

Title II of the act, originally introduced in Congress as a separate bill, contains provisions for refinancing farm indebtedness whereby excessive debts may be cut down, interest rates reduced, and payments on principal postponed. It provides means also for redeeming land which has been taken from farmers by foreclosure. Farmers whose mortgages are already held by any of the 12 Federal land banks also benefit directly by a reduction of their interest charges to 4½ percent for a period of 5 years. The measure appropriates \$15,000,000, and such additional sums as may be necessary, to reimburse Federal land banks for this reduction. Federal land banks may issue bonds up to \$2,000,000,000 on which the Government guarantees the interest. The act also appropriates \$50,000,000 which the Secretary of the Treasury may use in subscribing to the paid-in surplus of the Federal land banks. The orderly liquidation of joint-stock land banks is provided for, and a fund of \$100,000,000 is made available for loans to assist in this process. A loan fund of \$25,000,000 is also made available to these same banks to enable them to postpone foreclosures on delinquent loans. It authorizes and directs the Reconstruction Finance Corporation to make \$200,000,000 available to the Farm Loan Commissioner for direct loans on farm real estate, and to lend up to \$50,000,000 to agricultural improvement districts such as irrigation and drainage and levee districts. In addition, it permits the Reconstruction Finance Corporation to advance not more than \$5,000,000, on the request of the Secretary of the Interior, to complete authorized reclamation projects.

The National Industrial Recovery Act (Public No. 67, 73d Cong., approved June 16, 1933) authorizes the President to allocate not more than \$100,000,000 of the \$3,300,000,000 appropriated by that act for expenditures under titles I and II of the Agricultural Adjustment Act.

Methods Provided for Crop Reduction

The law, in title I, attacks the problem of the surplus. Ordinarily the producers would attend to the matter themselves, but circumstances prevent that. Often there is no escape from the farm, except into the ranks of the unemployed; and low prices compel competing producers to maintain the volume of their output. Farm production in the United States has not changed much since 1924, though the demand has fallen greatly. The only remedy is concerted action under central guidance, a course provided for in the law by several

methods, which include the leasing of land, the payment of cash compensation in return for output reductions, the cotton-option plan, and trade agreements to regulate production and prices.

These methods will be discussed in more detail in connection with the action taken under the law regarding wheat, cotton, tobacco, dairy products, etc., but an important feature common to them all should be emphasized here—they reach the individual farmer. Agricultural production in this country results from the decisions and actions of individual farmers, and farm production ultimately determines relative farm prices. It is therefore impossible to control the output except through the individual producer, by means that insure his cooperation through a balancing of inducements with responsibilities. Cash benefits under the law go only to the farmers that join in the effort to control production.

Along with the crop-reduction programs the act authorizes efforts to obtain for farmers a larger share of the consumer's dollar. Trade groups have an incentive to cooperate. Part of the consumer's dollar goes now to support wasteful and unnecessary competition, duplication of selling expense, a needless multiplicity of so-called services to consumers, dubious credit arrangements, and various unethical practices. Eliminating these wastes should mean better conditions for honest and efficient business, as well as better prices for producers. Giving farm commodities generally a purchasing power (an exchange value) in terms of other goods, equal to that which they had before the war, may in some cases involve higher prices to consumers. Fair exchange prices, however, should not work a hardship upon anyone; in fact they should benefit the community as a whole by improving the farm market for city goods and creating city jobs. For years now consumers have had farm products at less than cost. This is not good business even for the consumer. It threatens ultimately to dry up the sources of supply. Everyone has an interest in paying the farmers fair prices, in putting agriculture back on its feet.

The consumer has a right to expect, however, that the addition to his food bill shall go to the farmer, and to no one else. Generally other interests are not entitled to any part of the increase, because they have not suffered proportionately with the farmer in the slump since 1929. In order that the consumer may know that he is really helping agriculture when he pays a little more for milk or bread or cotton goods, the Agricultural Adjustment Administration will publish facts about spreads between consumers' and producers' prices.

Action by Farmers Indispensable

Agriculture's immediate prospects depend, of course, on many things besides what may be done under the Agricultural Adjustment Act. As the Industrial Recovery Act puts men to work, it will improve the domestic market for farm products. World wheat conditions may be helped by international action to reduce wheat acreage and to remove trade barriers. Cotton demand abroad may improve as the depression lifts. Our own administration's financial policy may raise the price level. Benefits that come to agriculture aside from its own efforts, however, may be temporary unless supported by thoroughgoing readjustments within the agricultural industry itself.

Production and marketing conditions for the different agricultural commodities vary greatly. Continuous change in economic situations makes any inflexible solution certain to be found unsuitable or ineffective after a comparatively short time. To deal with the many factors that contribute to the farmers' present situation, to deal with these factors as they apply to the commodities concerned, and to meet changes in the economic situation, the legislation grants broad and flexible powers. As already indicated, there is authority to provide for effective yet voluntary reduction in crop acreage, and to provide for a reduction in the amount of any commodity produced for market.

Briefly, the act is a program for economic planning—the first of its kind in the Nation's history. It contemplates the organization of producers for action which they cannot take individually, but which is necessary to substitute order for chaos in the agricultural industry.

The law seeks to build a regulated and properly balanced agricultural industry, with the forces of production bridled so as not to run rapidly beyond the demand, and to increase the demand by redistributing purchasing power so that it will come more readily into the market for consumable goods. It is a colossal job on lines not yet clearly defined. Broadly, the problem is to balance the agricultural industry internally and externally—internally by adjustment among its numerous enterprises, and externally by reducing total production and increasing consumer buying power.

Relation of Agriculture to Industry

In the post-war boom urban industry prospered much more than agriculture. It had a protected home market, whereas agriculture, with an overexpanded plant, had to meet world competition. In consequence nonagricultural prices rose much higher than agricultural prices after the first post-war slump. The disparity gave urban industry a temporary advantage. It could get raw materials cheap from the farm and had no need to advance wages equally with profits because living costs were low. In 1929 the rate of return on non-agricultural capital was about two and one half times the rate earned on agricultural capital. Even during the ensuing depression non-agricultural capital continued to earn on the average a bare return. Agriculture went heavily in the red.

The fact that urban industry prospered while agriculture did not gave rise to the notion that industry and agriculture had parted company, that the city could forge ahead independently, and that the old rule as to the identity of interest between the town and the country no longer applied. This was evidently a profound mistake. Industry and agriculture had not parted company. They never can do so. They had simply got out of step, while remaining harnessed together. When agriculture stumbled and fell, industry stopped with a jerk. It became clear that industry, by taking the products of agriculture at less than cost, had injured itself. If industry gets farm supplies for too little money, it loses agriculture as a market. The loss outweighs the gain. Farmers constitute an important part of industry's market, which sags heavily when farmers are not in it.

Permanent prosperity requires a fair exchange between the country and the town, not an unfair temporary advantage. It requires a balanced economy.

FARMERS AND NATIONAL RECOVERY PLANS

As part of the general recovery program the Federal Government has undertaken to raise the general level of prices through the control of credit and currency and through industrial codes designed to raise wages, increase employment, and improve labor conditions. These policies obviously affect the prices of the goods that farmers buy as well as the prices of the goods they sell. Raising the general price level decreases the burden of farm debts and taxes but does not necessarily give better relative prices for farm products. It is not a cure for all kinds of price disparity.

Steps that have been taken to raise commodity prices so that "those who have borrowed money will, on the average, be able to repay that money in the same kind of dollar which they borrowed" constitute an essential part of the national recovery program. Farmers have perhaps more interest than any other group in the restoration of the honest dollar. Controlled inflation now tends simply to correct the bad consequences of the uncontrolled deflation that followed the war. It is a means of promoting social justice through a fairer distribution of the national income. It lightens each farmer's debt and tax burden in proportion to the extent that it raises the prices of his products.

Monetary Action Alone Insufficient

Agriculture cannot, however, depend exclusively on a monetary policy to restore farm incomes. Depreciation of the dollar acts unequally on different agricultural products, as we have seen this year. It raises the prices of the export or speculative commodities such as wheat, cotton, and corn much more than it does the prices of milk, hogs, beef cattle, poultry, and other nonspeculative commodities sold mainly in the domestic market. Moreover, it also raises the prices of the things that farmers buy. Permanent farm relief has two principal requirements: (1) A rise in the general price level so that the burden of debt and taxes will be lightened, and (2) a closing of the gap between agricultural and nonagricultural prices. Only the first requirement can be confidently expected from controlled inflation.

If the general price level rises through monetary influences, without a proportionate change in production, supplies, and consumption, all prices and not merely prices to farmers respond eventually, though perhaps not uniformly. The disparity persists on a higher general price level. It is impossible for the Government, in its monetary policy, to single out any particular group of prices for special attention. By itself monetary action does nothing to change maladjusted situations for the better. Indeed, it may tend to prevent a favorable change by temporarily hiding the need. Inflation is not a cure-all. When it stopped, as sooner or later it would, we should again discover that the agricultural problem is one of balancing production with demand. It is of great importance that rising prices generally should not cause farmers to forget that favorable price relationships cannot exist in overstocked markets.

The proper handling of our money will help us reach a true state of balance, but there are certain fundamental factors which must be handled otherwise. To control these factors in the world of today with its multitude of trade barriers requires for the time a production control which is obnoxious to every class in our society. The farmer instinctively dislikes it; the railroads and commission men are against it, because it reduces the volume of their business; processors dislike it because of the processing tax; and consumers dislike it because it increases their cost of living. But the facts of the situation bear witness to the urgent necessity of curtailing farm production.

Effect of Codes on Price Disparity

Industrial codes under the National Recovery program had results that disappointed farmers at first. In many industries wages per hour rose as much as 50 percent. Manufacturers naturally sought to pass the increase on to consumers, including, of course, the farmers. As a result, prices paid by farmers for certain commodities rose sharply. Between March and October the average advance was more than 17 percent. Farm wages also advanced, following the advance in urban wages. Agriculture did not make the progress expected in reducing the disparity between agricultural and nonagricultural prices.

It is not likely that the immediate effect of the National Recovery program foreshadows its ultimate effect. We cannot judge what is essentially a long-time program from its initial results. The raising of wages and the shortening of hours in industrial employment delays correction of the disparity between farm and non-farm prices, but this should be only temporary. Industries that have increased their costs through higher wages and shorter hours will soon be adjusted to the new level of costs. The prices of their goods will be adjusted to it similarly, and should advance less rapidly or become stabilized. Agricultural prices on the other hand should continue to advance with adjustments in farm production and increases in consumer buying power.

It would be wrong to attribute the whole advance in nonagricultural prices to the intended and legitimate influence of industrial codes under the National Recovery Act. There has been some tendency for manufacturers and business groups to pyramid increased costs in consumers' prices. Many commodities are selling today at prices much higher than would be necessary to meet the expense involved in raising wages and shortening hours. It is an essential part of the National Recovery program that consumer buying power shall increase more than consumers' prices. Agriculture will suffer in proportion as this fails to come about. Recovery requires a balanced and approximately simultaneous gain in wage payments, consumer buying power, and farm prices. Keeping the recovery factors marching abreast is, however, an extremely difficult task.

Eventually the National Recovery Act should raise the prices of some of the things that farmers sell even more than it raises the prices of the things they buy through its effect on consumer demand. It should strengthen the market notably for products domestically consumed. Products largely exported will, of course, remain subject to world influence. The National Recovery program harmonizes

with the agricultural program to the extent that it increases total pay rolls, and to the extent that these pay rolls are spent for farm products. Restoring urban buying through increased employment, even if nonagricultural prices rise somewhat in consequence, is an essential part of farm relief. City workers must have increased incomes in order to pay more for agricultural goods. They will do so as soon as they are able, provided farmers do not continue oversupplying urban markets.

COORDINATING THE A.A.A. AND THE N.R.A.

It became necessary, after the enactment of the National Recovery Act, to coordinate work under the two laws. An Executive order on June 26 facilitated matters. The order delegated to the Secretary of Agriculture certain powers conferred on the President by the National Recovery Act. It placed under the Agricultural Administration all industries and trades engaged principally in handling milk and milk products, tobacco and tobacco products, and foods and foodstuffs. It covered all the powers conferred by the National Recovery Act over these industries, except the determination of labor questions. The situation thus being clarified, the Agricultural Adjustment Administration promoted various marketing agreements affecting agricultural commodities and accepted for consideration certain codes of fair competition proposed by the industries and trades mentioned in the Executive order of June 26.

Marketing agreements under the Agricultural Act have certain points in common with codes of fair competition under the National Recovery Act. Both laws authorize the licensing of everyone concerned, and both provide for the regulation of marketing. There are, however, certain important differences between the provisions of the two laws. Under the agricultural law, marketing agreements may raise prices to farmers and may give full exemptions from the anti-trust laws to all persons that comply with the terms. Certain provisions in the National Recovery Act might hamper the Agricultural Adjustment Administration's aims. For example, the National Recovery Act declares that no one may be prevented from marketing the produce of his farm and that codes shall not permit monopolistic practices. Furthermore the Agricultural Act extends to farmers whereas the National Recovery Act does not. Farmers cannot be parties to a code under the National Recovery Act. Marketing agreements reached under the Agricultural Act, plus codes of fair competition established in conformity with the requirements of the industrial law, may therefore include agricultural as well as industrial groups and may regulate production with the specific object of raising prices to farmers. The Agricultural Act, in short, is in some respects the broader measure.

Agreements Plus Codes

Many possibilities for combining marketing agreements under the Agricultural Act with codes under the National Recovery Act developed from the transfer of code authority over food industries to the Agricultural Adjustment Administration. It should be possible to apportion the resulting benefits with approximate equity. Mar-

keting agreements buttressed by codes have legal advantages which marketing agreements alone would not have. Such arrangements permit of rigid checks on the spreads between producers' and consumers' prices and of a scrutiny of operating costs, other charges, dividend policy, trade and group practices, marketing operations, price policies, and accounts. Agreements plus codes may coordinate the principal and the supplementary units within an industry. They may deal with the problem of competing units within an industry and with problems arising between that industry and related industries. They may take into consideration the relationship between particular agricultural industries and nonagricultural interests. Into the vast perspectives thus opened, it is difficult as yet to see very far. Certain general principles indicate the main policies which the Agricultural Adjustment Administration will necessarily follow.

It is of primary importance that marketing agreements or codes under the Agricultural Act shall tend to raise the prices received by farmers. This end may be sought through marketing agreements with or without licenses, or through marketing agreements supplemented by codes. There are some food industries which the Executive order of June 26 placed under the Agricultural Adjustment Administration and which have nothing to do with agriculture, as for example, the fish industry. In the case of such industries, the Agricultural Administration will merely perform a function for the National Recovery Administration. In all other cases it will treat the problem of regulation as inseparable from that of increasing the earnings of agriculture. It will probably be necessary in most cases to operate by agreements under the Agricultural Act, with codes under the National Recovery Act as a supplement, because it is only the Agricultural Act that authorizes the direct raising of prices to producers.

Farm incomes may be increased through marketing agreements in two principal ways, (1) by the direct raising of prices, and (2) by awarding to farmers some of the savings that food trades and industries may make through the lifting of the antitrust laws. It is manifest that profits thus created by the authority of a measure expressly designed to benefit agriculture should not remain exclusively with nonfarm groups. On the other hand the diversion to agriculture of all the savings thus realized would deprive the nonfarm groups of all motive to cooperate in promoting the object of the agricultural law. The matter is essentially one of agreement. It is a question of pooling and fairly distributing the economic gains that the law makes possible. This can best be accomplished through marketing agreements under the Agricultural Act.

Horizontal Agreements Desirable

It seems desirable, wherever possible, to have horizontal agreements or codes covering all the industrial units involved, rather than separate agreements or codes for small units in an industry. Industrial coordination and market balance cannot well be promoted without a close articulation of related trades. Vertical agreements or codes throughout the line of processing seem desirable also. Flour millers, wheat-starch manufacturers, and bakers, for example, should

be brought under a single agreement or code. This is necessary for both economic and administrative reasons. Separate agreements or codes for minute fractions of a food industry mean continuous and complicated readjustment of conflicting interests.

In some industries a general agreement or code is impossible. In such cases the next best thing is administrative centralization, such as has been undertaken in the dairy industry.

Arrangements concerning prices may take various forms in marketing agreements or codes. In certain cases, as in the milk agreements, prices both to producers and consumers may be established, with provision for periodic change. In other cases agreements may establish prices for producers and first processors or dealers. This has been done in the California peach agreement. In other cases agreements may regulate prices indirectly, through the allocation of supplies to shippers and the fixing of shippers' charges. Invariably it is necessary to consider supply and demand conditions. Prices fixed too high tend to stimulate production while restricting consumption and thus defeat the object in view. Agreements may also regulate trade practices so that unfair competition may be checked and wastes of various kinds eliminated. Agreements should promote efficiency in marketing, including processing and distribution, in order to insure the possibility either of higher prices or of returning to the farmer a larger share of the consumer's dollar.

Various expedients will advance the general objects of the marketing-agreement program. These include the collection and publication of facts about supply and demand, margins, and profits; the licensing of processors, distributors, and others; and the measurement of the savings that result from agreements. The agricultural act recognizes the interests of both the producers and the consumers. It contemplates raising the purchasing power of farm commodities to the pre-war level while protecting the consumer against extortion. It is obviously necessary to have methods of measuring and distributing the savings that result from marketing agreements. The development of the necessary accounting methods is a difficult matter and will take time. It must be done, however, because otherwise the benefits will inevitably drift into the wrong channels.

Price Regulation

Efforts to raise the prices of farm products by crop adjustments or marketing agreements should be distinguished clearly from attempts at price fixing. In certain of the adjustment programs launched this year, the administration included provisions for regulating prices. It did so in numerous milk agreements, and in agreements covering certain fruits. In all these cases, however, the price regulations went along with efforts to adjust production. It is necessary always to consider the effect of a given price level on both production and consumption. There are always high-cost and low-cost producers. In the absence of production control, prices high enough to maintain output on the high-cost farms stimulate output excessively on the medium- and low-cost farms. Meantime, such prices tend to restrict consumption. This is why price fixing alone always fails.

Commodity Credit Corporation

On September 22 the Administration adopted a loaning plan to assure farmers a return of 10 cents a pound for the unsold balance of the 1933 cotton crop. It established a Commodity Credit Corporation, with power to advance to any cotton grower 10 cents a pound without liability to him, provided he agreed to participate in the 1934 acreage-reduction program. Growers who participated in the 1933 reduction program received close to a parity return for their cotton; the loaning plan assures all growers a minimum return per pound and an opportunity to benefit from such gains as may result from higher prices to be brought about by the acreage curtailment for 1934. A similar plan was adopted for corn following the development of a corn-hog production-adjustment program. In States where corn may be stored under seal on the farm, with warehouse receipts as collateral, corn growers may obtain an advance of 50 cents a bushel Chicago basis, provided they agree to reduce their acreage in 1934.

In everything it has done, the Agricultural Adjustment Administration has kept in view the necessity of supporting prices by supply adjustments. It has not attempted so-called "price stabilization" by storing, for the sufficient reason that removing a portion of the supply temporarily from the market without preventing a rush of new production simply makes a bad matter worse. There is no magic by which prices can be fixed arbitrarily in complete defiance of the law of supply and demand.

FARM RELIEF AND THE CONSUMER

It is the declared policy of the Agricultural Adjustment Act to protect consumers as well as to raise the incomes of the farmers. While these objects seem contradictory, actually they go well together and indeed are interdependent. The law seeks to raise not merely the prices but also the purchasing power of farm commodities. Obviously this cannot be done if the prices farmers have to pay for various commodities advance excessively.

Farmers are consumers as well as producers; they make up at least 30 percent of the consuming public and have a common interest with consumers generally in getting goods at fair prices. They buy processed agricultural materials such as dairy products, hog products, cigarettes, and cotton goods. These things in their finished form include many elements of cost that do not figure in the raw materials. The intervening costs often greatly exceed the value of the raw materials. It is extremely important that false costs should not be added to true costs.

Farmers cannot be separated from other consumers and given special protection. All consumers must have protection. The farm recovery program includes protection for the consumer, not simply as a matter of justice to the general public, but as an aid to farm relief. Failure to keep consumers' prices in a sound relationship to producers' prices would prevent farm-commodity purchasing power from rising and would defeat the objects of the Agricultural Act.

Farm recovery requires, in short, that producers' prices shall rise more than consumers' prices—in other words, that spreads between

country and city prices shall be reduced. These spreads are generally wider now than they were before 1929, and universally wider than before the war. Manufacturing and distribution took a steadily increasing share of the consumer's dollar between 1910 and 1929. In the case of milk the share increased from 56 to 62 percent; in the case of bread, from 74 to 81 percent. On the average the retail prices of foods increased nearly 70 percent during this period, whereas the farm prices of foods increased only 36 percent. After 1929 farm prices dropped much more than retail prices. The spread between the country and the town prices increased proportionately.

Redistribution of purchasing power to wage earners and crop adjustments in agriculture cannot be relied on exclusively to correct the trouble. These factors should help to bring supply and demand more nearly into balance. Processors, distributors, and others, however, hold a strong position in the economic system. They can continue to exact an undue share of the consumer's dollar, if nothing is done to stop them. Codes and marketing agreements, unless very carefully drawn, may serve to perpetuate unbalanced conditions. In seeking the cooperation of processors and distributors in arrangements to pay increased prices to farmers, the administration must allow these groups a profit. It is extremely difficult not to be drawn beyond that point.

Regulation of Margins

Restoration of a good balance in the economic system may require more than allowing fair prices to farmers without charging the consumers prices exceeding the fair exchange value prescribed in the Agricultural Act. Some pending agreements that do that nevertheless permit increased profits to processors and distributors. Such increases generally would obviously work against the purposes of the Agricultural Act and the National Recovery Act and would counteract the desired redistribution of purchasing power. Regulation of production and of producers' prices would seem to require, as a logical corollary, the regulation of profits. When profits increase greatly out of proportion to wage payments, consumption inevitably falls. Farm returns fall in consequence. It is necessary to arrange matters so that processors and others who, under marketing agreements and licenses, are required to pay increased prices to farmers shall not add more than that increase in their prices to consumers. Usually they can well afford to add less.

This question of profits goes, of course, beyond the industries that handle agricultural products. Stability in our industrial as well as in our agricultural life may depend on answering it correctly. It may be necessary to review very critically the influence of excessive profits on our economic life. Farmers know well that sharply rising farm prices produce expansion which shortly brings prices down. Similarly, unbalanced expansion results in industry from temporarily high profits, so that the profits eventually are wiped out. In both agriculture and industry a better total return would probably result, in the long run, from prices and profits that fluctuated less. One gain would be a drop in speculation, which thrives on instability. It is not high prices or high profits that cause speculation, but changing prices and profits. Methods that prevented undue fluctuations would be more powerful than many laws in curbing speculation.

But more important than the prevention of speculation is the distribution of income in such a manner as to close and not widen the gap between production and consumption. Excessive margins between producers' and consumers' prices tend perhaps as much as anything else to destroy the balance.

FARMERS AND UNEMPLOYMENT RELIEF

Farm relief through unemployment relief became part of the national policy in September with the organization of the Federal Surplus Relief Corporation. This governmental agency, in cooperation with the Agricultural Adjustment Administration, purchases surplus agricultural commodities for distribution to the unemployed and their families. It transfers surplus foods and other farm products directly to needy people, in such a way as to increase the farmers' net return. Agriculture's difficulties result in part from production in excess of consumers' needs and in part from underconsumption. Low farm prices partly reflect the curtailed demand of the unemployed. By diverting excess supplies to those who cannot buy, the Government helps farmers to get better prices from those who can buy.

Funds are available to the Federal Surplus Relief Corporation from congressional appropriations and from loans from the Reconstruction Finance Corporation. Proceeds of processing taxes levied on farm products under the agricultural act may partly finance the operation where it appears that the resulting improvement of the farmers' market, through the reduction of surpluses, will justify such action. For some products farmers will obtain better returns after a portion of the supply has been diverted. They will get more for what remains for disposal through the usual commercial channels than they can possibly obtain with these channels glutted. There may be some commodities that would not respond in that way to the diversion of supplies from commercial to charitable uses. In such cases the Administration would not be justified in attempting to finance the operation through processing taxes, but it could properly use funds available from other sources.

This policy strikes at the cruel paradox of want in the midst of plenty. Farmers particularly are conscious of this paradox. They approve the distribution of surpluses to the needy and merely ask that the Nation as a whole shall bear the cost. In periods of great overproduction in agriculture, the farmers themselves carry most of the burden of relieving distress. They do it through the harsh necessity that compels them to part with their entire production at less than cost. Practically, they give away much of what they produce. Hence the new relief program serves agriculture in two equally important ways. It partly frees farmers from a continual unfair drain upon their diminished resources and satisfies their feeling that people should not be allowed to starve when granaries and warehouses are bursting.

PERMANENT CONTROL OF AGRICULTURAL PRODUCTION

The present program for readjusting productive acreage to market requirements is admittedly but a temporary method of dealing with an emergency. It could not be relied on as a permanent means

of keeping farm production in line with market requirements. From a national standpoint it has the disadvantage that it takes out of production both the efficient and the inefficient areas. Moreover, it carries no insurance against the expansion of production through bringing new lands into cultivation under the stimulation of the better prices achieved by curtailing production in areas now cultivated. With separate programs of control for different products, it is difficult, without severely restrictive measures, to avoid the shifting from one controlled product to other products. The need of annual campaigns for acreage reduction and of the various measures to prevent evasion involves complicated and expensive administration.

A temporary and varying reduction in the productive acreage seriously disturbs the farm economy; it may modify established rotations and feeding practices; it requires readjustments in the relationships of landlords and tenants, which may be disadvantageous to the tenants; and it necessitates the disuse or less effective use of the labor, machinery, work stock, and the equipment acquired to farm larger acreages. Overhead costs frequently cannot be curtailed in proportion to the reduction in farm operations.

Generally it must cost more to induce farmers to keep a portion of their farms temporarily idle than it would cost to rent a corresponding acreage by taking over entire farms. This may not be the case where the aim is to reduce the acreage in a single crop, in sections where that crop is but a small proportion of the total productive acreage in the farm. If, however, the aim is to reduce the farm plant as a whole, in order to deal with a tendency toward surplus production in the principal staple crop and livestock products, it will generally be less expensive and more economical even in such areas to acquire entire farms.

This conclusion may be illustrated by the situation in 14 hard winter wheat counties of Kansas, in which wheat occupies over four fifths of the land in harvested crops. Under the present recovery plan the cost of reducing the wheat acreage by 15 percent is between 17 and 36 percent of what it would cost to buy the farms outright and six times as much as owners leasing for the very liberal rent of one third of the gross production would get from their share of the wheat priced at 50 cents on the farm.

Relative Cost of Leasing and Buying

In the long run, it would be cheaper for the Government to purchase farms than to lease them. For one thing, the rate of interest that the Government pays for money is considerably less than the percentage of rental value of farms to the capital value. In 1932 for the United States, exclusive of the Cotton Belt, cash rentals of farms less taxes averaged between 6 and 6½ percent of the value of the farm real estate. In the Cotton Belt the average was higher but was complicated by special conditions of risk and responsibility. In the North Central States, where in general there has always been a tendency toward a comparatively low ratio of net rentals to values, the ratio in 1932 ranged by States from 4.33 to 6.09, averaging a little over 5 percent for the 12 States. Furthermore, the Government purchase of farms would give greater permanence of control of par-

ticular areas and a greater possibility of developing a consistent and stable policy of utilization.

This comparison of the relative cost of acquiring entire farms and of subsidizing acreage reduction within operated farms does not necessarily mean that it would be desirable to purchase immediately an area of farm land corresponding in total productivity to the area removed from cultivation under the present emergency program. That would avoid one difficulty but would create another. While reducing the farm surplus, it would increase the labor surplus. The emergency program for reducing farm production is dictated partly by the existence of huge surpluses gradually accumulated. When these surpluses diminish, less restriction of production will be necessary. Restriction will become still less necessary as the domestic demand for farm products revives.

But our farm plant will probably continue to be too large for commercial production. The economic conditions and restrictive policies that have curtailed the European demand and the subnormal domestic demand may not change for the better quickly. It is therefore necessary to consider gradually reducing and controlling the size of the farm plant as a whole as a means of supplementing and in some measure displacing the emergency policies. This can be accomplished by removing from cultivation the farms which are economically and socially least desirable, such farms as are loosely termed "submarginal."

Advantages of Eliminating Lean Acres

Eliminating the lean rather than the fat acres is desirable for many reasons besides that of reducing production. Generally, the cultivated areas most subject to water or wind erosion are those which would also be classed as poor, frequently as a result of previous erosion. In many cases, under present conditions the individual farmer cannot do what is necessary to check erosion. In certain parts of the country there are poor lands in use which may be regarded as "nuisance" areas from the standpoint of the community. These include lands that serve as breeding grounds for insect pests and plant diseases and isolated farm units within national forests. Such isolated farms sometimes enhance the fire hazard and complicate problems of administration. In some areas the natural resources are so ill-adapted to farming that the standard of living remains at a poverty level. These areas depend from time to time on governmental seed loans or relief funds.

Poor schools and roads usually characterize areas of poor farm land, though sometimes more prosperous sections contribute to the school and road funds of the poor districts. In other cases the provision of schools and roads has involved the assumption of a local tax burden tolerable only in prosperous times. In many such areas during the depression there has been a serious breakdown of the local fiscal system, aggravated by tax delinquency, farm abandonment, and the passing of forest resources. A program for gradually removing poor farming areas from cultivation appears desirable to correct many economic and social maladjustments of both local and national significance, as well as for bringing our farm plant to manageable proportions.

In line with this principle is an agreement between this Department and the Public Works Administration, which provides that, for every acre of new land brought into cultivation through reclamation by public works' funds, money shall be made available to take out of cultivation an area of poor farm lands of corresponding productivity. In general the acreage of poor farm land thus removable will amount to several times the area of newly reclaimed land. Funds will be made available for studies to determine the areas that should be removed from cultivation.

In this work the Department will have in mind not only a reduction of the farm plant but also the other considerations above mentioned. It will consider the institutional and fiscal readjustments which the withdrawal of land from cultivation will involve. Land socially and economically unsuited for farming may be considered for purchase by the appropriate public agency for use as public forests, parks, or regulated grazing districts.

Federal and State Cooperation

Land-use planning vitally concerns State and local agencies as well as the Federal Government and should be developed in close cooperation with such agencies. It is important to keep poor new land out of cultivation. Short of public purchase, the main practicable method is through State policies of grants-in-aid and the exercise of the zoning power. These and other considerations emphasize the importance of Federal cooperation with State and local authorities.

When there is much unemployment, it is not always advisable to remove families even from poor land, where they may at least get food, shelter, and fuel. But many families are stranded on poor land and would welcome opportunities for favorable relocation. Recovery from the depression will open opportunities in industry for some now living under bad conditions in the country.

But the problem of farm people stranded on land too poor to furnish a decent living represents but one phase of the problem with which economic planning must reckon. In our eastern coal fields at least 200,000 miners are permanently displaced, through the mechanization, exhaustion, or closing of the mines. There are said to be 5,000 stranded copper miners in Arizona and 15,000 oil-field workers stranded in the Southwest. There are many lumber towns in the State of Washington left to a precarious struggle through the removal of the timber.

Many of these workers came originally from the farm. Industry and the cities formerly provided an outlet for thousands of rural young people annually. In 1880, 71 percent of the population of the United States was classed as rural, in 1930 but 44 percent.

Industrialization and the rush to the cities may have gone too far. We may be entering a prolonged period of urban unemployment. Older workers have difficulty in retaining the jobs for which they were trained. A miner is said to be through at 45. Many industrial and commercial concerns draw the employment line at about 45 to 50. But such men should not be thrown on the scrap heap. There are many kinds of work which they can do for wages, at least on a part-time basis. The younger workers face the shorter

work day and work week. How much unemployment is technological and how extensive unemployment from this cause will be in the future, we cannot tell. In the long run the men displaced by machinery may be needed to make the machines that displace them. But meanwhile they must eat.

Underlying both urban unemployment and agricultural distress is the need of fundamental readjustment to a changed condition. The subsistence problem is not confined to the cities. One out of seven rural families now receives relief. These people, urban and rural, should have a chance for self-help, a chance to become self-supporting.

Congress attacked the problem in section 208 of the National Recovery Act. This section provided \$25,000,000 to redistribute population through loans or other aids to the purchase of subsistence homesteads. Thousands of city people, unable to get work, have struck out for themselves and gone back to the land. But a wholesale and blind movement is hazardous, both to the participants and to agriculture and rural communities. It is necessary to guide and direct the return to the soil, as well as to aid it financially, a task which has been entrusted to the Department of the Interior.

In the program to carry out the purpose of section 208 emphasis will be placed on experiments in aiding workingmen to establish garden homes within commuting distance of factory and office, so as to provide them with shelter and an opportunity to raise much of their own food, and at the same time permit them and the members of their family to work in industry and trade. Such a movement "halfway back" to the land has already gone on for a number of years in New England. The automobile, the modern highway, and the electric power line facilitate it. It provides a measure of security in times of unemployment. It should not injure the commercial farmer by seriously adding to the surplus of our agricultural staples. Indeed it may aid him by giving the worker security and stabilizing urban purchasing power.

The program may also encourage the decentralization of those industries that are economically adapted to small units located in the smaller towns and villages. Centralization in huge plants appears to have gone too far. Moreover, this country imports many products that could advantageously be manufactured here in small plants. Plans for redistributing population should include the relocation of farmers now stranded on hopelessly poor land. This should be done in connection with a program for retiring such lands from cultivation. In the past such badly located farm people continually drifted to the cities.

If much urban unemployment should persist for a long time, farm policy may be required to provide for the thousands of young people who annually leave even good farms for the cities. The annual increase in the Nation's population now depends mainly on the natural increase of the farm population. This averages about a half million a year. For a decade preceding the present depression, the resulting annual surplus of farm people was drained away into other employment. Failing reopening of this outlet, steps must be taken to provide means whereby the half million farm people who each year reach working age may earn a living. It may be necessary to modify our former ideal of a highly efficient commercial agriculture, and to

facilitate so-called "subsistence farming." Such farming would have less commercialism but a greater degree of economic stability than now prevails in many farming areas. Such a policy, as well as all policies to aid in placing more people on the land, would have to avoid as much as possible intensifying agricultural competition.

SCIENCE IN PRODUCTION AND IN DISTRIBUTION

In these efforts to balance production with demand, and to prevent useless farm expansion, it may seem that the farmer has a quarrel with science; for science increases his productivity and thus tends to increase the burden of the surplus.

Some farmers take this view. They believe we got into the present economic jam partly as a result of technical efficiency. They ask why Government agencies help farmers to grow two blades of grass where one grew before and simultaneously urge them to cut down their production. They declare it is almost criminally negligent for a Government to promote an increase of production, without facing the results of that increase. These ideas lead to something of a revolt against science, and to demands for a halt in technical progress until consumption catches up with production.

It is undeniable that science creates problems; but the remedy is not less but more of the disturbing ferment. What we need is not less science in production, but more science in distribution, and this means distribution of wealth as well as of the physical products.

Science has magnificently enabled mankind to conquer the problem of producing enough to go around. It has now to help us utilize the increased productivity.

This is the special province of economics. It is a difficult field, because the data include facts of psychology, of politics, of history, of race, and even of religion, as well as of production and demand. Reducing such diverse facts to order is harder than discovering relationships among chemical elements isolated in a test tube. The economist cannot fix his material; he must deal with the living, changing, dynamic world. But the difficulty does not excuse evading the problem. It cannot be evaded.

Gain in Farm Productivity

In agriculture, science has increased tremendously the productivity of the farm operator, without giving him equal help in disposing of the result. Note a few cardinal facts. Our total crop acreage showed no increase in the decade from 1919 to 1929. This was the first decade in our history that recorded no expansion. The number of horses, cattle, and hogs on farms declined somewhat, and there was a decrease also in the number of farms and in the farm population.

Yet the farm output, instead of declining, increased amazingly. It rose about 20 percent, whereas the country's population increased only 16 percent. In consequence our people, during the first half of the decade at any rate, lived better than ever before. They consumed about a fifth more milk per person, a sixth more pork, and probably a fifth more fresh vegetables and fruits, but less corn, rye, and wheat bread. The increased farm production, since it took place in a declining market, impoverished agriculture.

The wheat farmer in the Great Plains has at his command in the tractor and the combine the power of 300 men. He can cultivate 1,000 acres and feed 2,000 people. The corn grower has new inbred strains of corn developed in this Department and in the State experiment stations which give promise of producing the Nation's present supply of corn on 90,000,000 acres instead of 100,000,000. By fertilizing only to a profitable extent, and by a more general practice of efficient crop rotations, it would be possible to get the present corn supply from 70,000,000 acres. Moreover, this saving of land would save half a billion hours of man labor annually and would save from erosion hilly land which is now washing into the rivers.

Cotton-picking machines now being used in Texas and Mississippi seem likely to be perfected. If they become a commercial success, the acreage of cotton that one man can handle will increase to 100 or 200 acres. The present average is 20 acres in the eastern Cotton Belt and 40 acres in the western Cotton Belt.

In 1929, according to the census, about half the farms in the United States produced 90 percent of the products "sold or traded." This implies that nearly half the farmers are not needed to supply even the present commercial demand. They may be usefully occupied, to be sure, in supplying part of their own wants. Further scientific progress will enable a still smaller number to produce as much as the market now takes.

Science has achieved great triumphs in animal industry. Records of the dairy herd-improvement associations partly tell the story. These associations are organizations of dairy farmers who employ cooperatively a tester to determine the amount of milk and butterfat produced by every cow owned by their members, and to compute the cost of feed. The records help in the selection of herd sires, in the rearing of young stock, in feeding and care, and in herd culling.

In 1920 the production of butterfat per cow in the dairy herds owned by the members of 452 associations averaged 247 pounds a year. By 1928 the average had risen to 284 pounds; by 1930 the average for more than half a million cows on test was 302 pounds per cow; and by 1932 it was 310 pounds. Twenty-five years of record keeping showed a gain of 95 pounds per cow.

The dairy herd-improvement program benefited dairy practice generally. In 1900 the average production of butterfat per cow was 145 pounds a year; in 1930 it was 180 pounds. In the 5 years preceding the depression the number of dairy cows in the United States was only about 5 percent greater than it was 10 years before. The production of milk was fully 25 percent greater, yet the consumption of feed increased probably less than 15 percent.

It was science and education that brought about this increased efficiency—science expressed in plant and animal breeding, in improvements in animal husbandry, and in the use of machinery and power on the farm; and education carried to the farmer by Federal and State agencies, and by the agricultural press.

Scientific Victory Incomplete

Nevertheless the scientific victory was incomplete. When science increases the farmer's power to produce without enabling him to regulate his production, and without finding new uses for the land

and labor which the improved technic releases, it does only half a job. The remaining half is to match the technical achievement with economic achievement, and to parallel the progress in production with progress in distribution.

Gains in technical efficiency, if not supported by scientific adjustments in our economic system, throw society out of balance and bring its complicated mechanism to a grinding halt. We need economic machinery corresponding in precision, in power, and in delicacy of adjustment to our technical machinery.

Population statistics warn us that the problem is urgent. Both in the United States and in Europe the birth rate has dropped; and this country has checked immigration. Ten years ago our population was increasing nearly 2,000,000 a year; now the increase is only about 800,000. England and Germany, formerly great markets for American farm products, will probably have stationary populations within a decade, and eventually declining populations. It now appears that the population of the United States will probably cease to expand about 20 years hence. It is significant, too, that the consumption per capita of many farm products has shown a decline in recent years—a 10-percent drop since 1928. How can we reconcile increasing productivity in agriculture to a declining demand? This is the supreme question of our time.

It is vain to propose letting inefficiency take over the job of reducing the volume of the surplus. Man is not built that way; if he were, he would still be in the primeval mud. Putting a brake on science is not the solution. Farmers realize that competitive necessity forces them to keep up to date. Failure to do so puts them at a disadvantage not merely in world trade but in home trade, because efficient production from abroad enters into the situation. A return to more primitive methods of production, or even neglect to keep abreast of average technical efficiency raises costs more than it raises prices.

The problem is to adjust production to the existing effective demand, to divert productive power from the creation of surpluses to the satisfaction of wants, and to open new channels into which economic energy may profitably flow. As an emergency-relief measure, it is fitting to reduce production; but the ultimate solution requires an increase in consumption, so that we may establish an economic balance that can be maintained.

Problem of Distribution

It is essentially a problem of distribution. We have surpluses, in industry as well as in agriculture, largely because the laws that govern the distribution of income cause a polarization of wealth and poverty, a piling up of purchasing power at one end of the social scale. In consequence a majority of the people spend all their money before they have satisfied their wants, while a minority satisfy their wants long before they have spent their money. There results an unemployed block of purchasing power which tends to be transformed into capital and to go back into production instead of entering the market for consumable goods. This makes the surplus situation worse.

Potentially, the purchasing power existing at any time equals the supply of goods; but it does not necessarily enter the market for

those goods. To make it do so, it must be joined to need or desire. When purchasing power gravitates away from need or desire, it lies idle or runs to waste in speculation and bad investment. How much more socially intelligent it would be to redistribute purchasing power in such a way as to put it effectively to work. Unemployed purchasing power means unemployed labor and unemployed labor means human want in the midst of plenty. This is the most challenging paradox of modern times.

COTTON-ACREAGE REDUCTION

The need was specially acute this year for controlling the production of cotton. In the marketing season 1932-33 the total supply of American cotton was no less than 26 million bales, half of it from the carry-over and the other half from the 1932 production. Our cotton production had been maintained at a fairly high level since 1929, despite a sharp drop in the world's consumption of American cotton. In 1930-31, for example, the consumption was only 11,000,000 bales, as compared with 15,000,000 in 1928-29. Cotton prices to farmers in February 1933 averaged 5.5 cents a pound. The low point was reached at 4.6 cents a pound in June 1932.

These figures may be compared with the prices received by farmers in the years immediately following the war, because farm expenses including interest and taxes had declined only moderately from the post-war peak. Farmers received an average price of 35.2 cents for their cotton in 1919-20, of 28.7 cents in 1923-24, and 18 cents in 1928-29. In the general price situation that prevailed in the first half of 1933, cotton prices to farmers should have averaged 12.7 cents a pound to give cotton its pre-war exchange value. This price for cotton was therefore provisionally the objective of the cotton-adjustment program.

Circumstances early in 1933 pointed to a worsening of the cotton-surplus problem. Growers felt driven, despite the disastrously low price of their staple crop, to increase the acreage devoted to it. They had no other cash crops to which they could profitably turn, and the necessity to grow something for revenue was compelling. The low unit price of cotton obliged the farmers to think about having more units to sell. Accordingly, they planted 40,798,000 acres to cotton, as compared with 35,939,000 acres harvested in 1932.

In view of the peculiar conditions, this was not an abnormal increase. It was, however, somewhat larger than price analysis had predicted. It was renewed evidence that the law of supply and demand, which is supposed to curtail production when prices are low, does not always have that effect, particularly in agriculture. Under extreme pressure farmers operating competitively act in a manner exactly contrary to their collective interest. They increase production when it should be decreased. Many former attempts to adjust farm production came to shipwreck on this particular reef. Farmers who were inclined to cooperate faced the knowledge that if they did they would have less cotton to sell than usual, whereas noncooperators would probably have more.

Above-Average Yields Indicated

On the acreage originally planted to cotton this year, average yields would have given a production of 13,900,000 bales or thereabouts. As the season advanced, it became clear that the yields would be above the average. The October report of the Crop Reporting Board estimated 205.3 pounds per acre as compared with a 10-year average of 167.4 pounds. Had the crop been allowed to mature on all the acreage planted, the production would have been approximately 17,135,000 bales (according to the indicated yield as of October 1)—the second largest crop on record. With such a crop, the price of cotton would inevitably have declined again. Against the weight of an increasing supply already much too large, the commodity could not have held its place in the general advance of prices that has resulted from the Government's monetary and industrial policies. While other farm-commodity prices were climbing, cotton would have entered upon a new decline. It need scarcely be said that such a development would have meant utter ruin for thousands of cotton growers and additional distress for the South and for the Nation as a whole.

Shortly after the enactment of the Agricultural Adjustment Act, the Adjustment Administration held a conference with the directors of extension of the 16 cotton States. They recommended action under the new law to eliminate at least 30 percent of the planted cotton acreage. At another conference, growers, manufacturers, and handlers of cotton made a similar recommendation. Accordingly, on June 19 the Administration announced a program of cooperation between the Government and the cotton growers. It offered two plans: (1) A cash payment per acre to the individual farmer in return for an agreement to reduce his cotton acreage; and (2) a cash payment per acre plus an option to buy, at 6 cents a pound, a quantity of Government-owned cotton equal to the farmer's reduction in output. These payments were to vary with the prospective yields per acre. More was to be paid for high-yielding than for low-yielding land. It was the theory of the option plan that cotton, as a result of the acreage reduction and also of the Government's general recovery policy, would rise in price sufficiently to give the option holders a satisfactory profit.

These plans, the Adjustment Administration announced, were to go into effect if a sufficient number of cotton growers offered to reduce their acreage. It was felt that the prospective output should be reduced at least 3,500,000 bales, the normal production of about 10,000,000 acres. Through the Extension Service and with the assistance of 22,000 voluntary workers, it proceeded to sign up growers in formal contracts to reduce their acreage in return for specified payments. This was a tremendous task. The physical difficulty of getting contract forms and other data into the field taxed available facilities to the utmost. It became necessary to extend the time originally allowed for the farmers to make offers of acreage reduction. Offers were received up to midnight July 12. The signing of each offer required recommendations from the county committee and the county agent, after proper inspections of the acreage involved. Everything possible was done to prevent fraud and to keep producers

from overestimating their yields. Farmers responded generally. On July 14 the Administration announced that sufficient acreage had been offered to warrant putting the program into effect.

Estimated Acreage Withdrawn

Estimates in September indicated that 1,031,000 cotton producers had contracted to withdraw 10,396,000 acres, on which the production if the crop had been allowed to mature would have exceeded 4,300,000 bales. The acreage offered, and the reduction in production, ran materially above the minimum established as necessary. The cash payments averaged about \$10.60 an acre and aggregated approximately \$110,000,000. Straight cash payments varied from \$7 an acre for land producing 100 to 124 pounds to \$20 an acre for land producing 275 pounds or more per acre. Under the plan calling for a cash payment plus a cotton option, the cash payments ranged from \$6 an acre for land producing 100 to 124 pounds, to \$12 for land producing 275 pounds or more. Participants in the option plan will have in addition the difference between the purchase price and the selling price of the option cotton. There has been a margin in their favor consistently since the plan went into effect. The option contracts provide that holders may not dispose of their cotton at less than 9½ cents a pound prior to December 1, 1933. They may call their options at any higher price up to that date or may renew them up to May 1, 1935, by paying the carrying charges (estimated at 40 cents a month per bale). This applies to the period from May 1, 1934, to May 1, 1935.

In preventing the cotton planted on 10,396,000 acres from maturing, the growers who cooperated with the Administration besides strengthening the cotton market, manifested a spirit that augured well for the success of future control operations. They estimated their prospective yields very moderately. As already noted, the average yield of cotton per acre for the United States as a whole was estimated by the Crop Reporting Board in October at 205.3 pounds. The October forecast of production was 12,885,000 bales. On the acreage withdrawn from production, the withdrawal contracts fixed the probable yields at an average of only about 184 pounds. This is the more striking when we bear in mind the fact that the worst lands were rejected.

The Administration accepted no land that did not give evidence of producing more than 100 pounds per acre. It refused flooded or droughty land. In checking the farmers' offers, the Administration obtained statements of the 1932 production and checked these statements at the gins. Some farmers reported their 1932 production as less than the gin records showed they had ginned. Growers complied wholeheartedly with the need to destroy completely the cotton on the acreage covered in their contracts. Reports of failure to comply with the requirements of the program were extremely rare.

Cotton Processing Tax

In accordance with the provisions of the Agricultural Adjustment Act, the Administration announced a cotton processing tax effective August 1. It fixed the tax at 4.2 cents a pound, the difference be-

tween the farm price of cotton on June 15 and the fair-exchange value of cotton on that date. As defined in the law, the fair-exchange value is a price that will give cotton a purchasing power in terms of other commodities equaling its purchasing power in the pre-war base period—August 1909 to July 1914. The processing tax is intended to defray the costs of the acreage reduction. It applies to the first domestic processing of cotton—specifically to spinning, manufacturing, or other processing except ginning. It does not apply to linters. In addition, the Administration placed a tax equivalent to the processing tax on all articles manufactured wholly or chiefly of cotton that were in stock on August 1, 1933. It excepted retailers' stocks, unless they were held until September 1. Retailers therefore had 30 days in which to dispose of their stocks without paying the tax.

It is expected that these taxes, in the main, will be passed on to consumers, whose power to pay them will be increased by the Government's general recovery program. There is no way to determine the extent to which prices to consumers will be raised. Consumers' prices have risen already from the low levels that prevailed last winter. Part of the increase may be attributed to the increase in manufacturing costs necessitated by adherence to codes of fair competition. Part may reflect inflation. Part may have resulted from the processing and floor-stocks taxes—it is impossible to measure separately the relative influence of these different factors. However, the taxes are low compared to the total cost of cotton goods to consumers. Furthermore, the law requires the Agricultural Adjustment Administration to prevent unfair pyramiding of the tax in consumers' prices.

Some Probable Results

As to net results of the whole campaign, it is too early to speak. Nature produced cotton abundantly this year and thus complicated our task. Cotton suffered much less from the drought than did the main northern crops. The new crop, added to the carry-over of something less than 12,000,000 bales, gives a supply of American cotton larger than that of any year prior to 1931. It gave a supply of approximately 10,000,000 bales in excess of the world's consumption in 1932-33, and far above any probable consumption in 1933-34. The reduction of acreage this year merely prevents the surplus from growing oppressively larger. It does not by any means sufficiently reduce the oversupply, and the situation in the Cotton Belt remains critical.

In all probability, however, the withdrawal of 10,396,000 acres from production benefited the cotton-price situation more than may appear. It is a truism that overproduction depresses prices cumulatively. Each addition to the supply forces prices down with a disproportionately increasing effect. The same principle works in the opposite direction. Removing the top of the surplus has a proportionately greater beneficial effect than removing equal amounts later. It may reasonably be concluded, therefore, that the 1933 cotton-reduction campaign achieved as much as could have been expected, in view of the unexpectedly large production on the acreage remaining for harvest. More important still, it blazed the trail for more extensive efforts in the future.

It must be remembered that the 1933 campaign started under certain unavoidable handicaps. In the first place, it followed an unusually liberal crop-production loan program, which had been set in motion earlier. There is nothing essentially wrong about arranging production credit for the farmer, but it needs to be linked up with the acreage-reduction program. Hereafter it will be important to handle production credit in harmony with crop control. Secondly, the season was far advanced before acreage-control action could be taken. The Agricultural Adjustment Act was approved May 12, but essential amendments to it in the National Recovery Act did not become law until June 16. By that time much of the cotton crop was in the ground. As previously mentioned, it was July before the acreage-reduction plan went into operation. Up to that time the farmers had obeyed the customary incentives to maintain production as an offset to low prices, and the amount of acreage reduction necessary to influence the market in the required degree was much greater than would have been the case had it been possible to announce the plan before planting time.

Cotton prices started to advance in the spring, along with the decline in the gold value of the dollar and the growing evidence that measures would be undertaken to control the production. By the beginning of the 1933-34 marketing seasons, prices to producers had risen to above 10 cents a pound. From the peak, however, the prospect of heavy yields and other influences caused a reaction. In consequence the fair exchange value, at this writing, is not in sight.

Need for Long-Time Program

Certain conclusions may be drawn from these facts and from the general cotton situation. It is necessary to have a cotton program covering not simply one season but several seasons. The cotton surplus was not created in one season, nor will it be removed in one. Adjustment of cotton production to the demand is essentially a long-time proposition. It cannot be achieved by hasty improvisations based on weather indications at the beginning of a single season.

In the 1926-27 season the United States produced 17,978,000 bales; in the succeeding season it produced only 12,956,000. Yet the harvested acreage dropped only from 44,616,000 to 38,349,000 acres. It was nature that mainly determined this great change in the volume of production. Such facts are common, and growers are so impressed by them that they are often pessimistic as to the possibility of regulating production. In the partnership between man and nature, they imagine that nature has the deciding voice.

This is not the case. It is only for brief periods that nature seems to decide the matter. In the long run the action of the weather and other natural influences is surprisingly uniform. Favorable conditions in one season offset unfavorable conditions in another. Over a term of years the deciding factor in the volume of production is a controllable factor, namely, the acreage. In the period 1898-1902 the cotton area of the United States averaged 25,675,000 acres, and the production 10,176,000 bales. In the period 1927-31 the cotton area averaged 41,036,000 acres and the production 14,657,000 bales. Production increased with the acreage, falling a little behind because the invasion of the bollweevil and other factors reduced yields

somewhat but remaining in a very stable relationship with the acreage. Over a term of years the growers decide how much cotton shall be produced.

As an emergency proceeding, the course taken in 1933 met the requirements successfully. It need not on that account be taken as the necessary basis for a long-time policy. Farmers this year plowed up cotton after it was planted, an action much against their instincts. It seems obviously preferable to have an agreement in advance, so that what should not be grown will not be planted.

Plan for 1934 and 1935

The 1933 program prevented a disaster, but it was only the first step in the control of cotton production. It is planned in 1934 to limit the acreage to approximately 25,000,000 acres.

At conferences with representatives of the Agricultural Adjustment Administration growers and others interested endorsed the plan, which may be extended into the 1935 season. A committee representing nine cotton-growing States recommended immediate announcement of the program, so that growers would have ample time to prepare for it. Accordingly, the Administration issued an outline of the project on September 22.

It is intended to reduce the number of bales or the net production, and the allotment principle is applied. Acreage rentals will be paid on the land left out of production, plus benefit payments in amounts tending to give participating producers an income representing pre-war exchange value on the domestically consumed proportion of their crop. It sets 25,000,000 acres tentatively as the figure to which the total cotton area should be reduced, but the real object is a decrease in the output. The plan will be administered with that end in view.

Acreage to be planted will be allocated among cotton-producing States on the basis of a ratable proportion of the 5-year (1928-32) average. To each county will be allotted its ratable proportion of the State's average.

County allotment associations will be formed to allocate to each farm operator his proportion of the county allotment. If land has not been planted to cotton continuously, the production of adjacent or similar land will furnish the basis for allotments and payments. The Secretary of Agriculture may prescribe uses for the acreage rented and may limit or restrict the crops to be produced thereon.

No rental or benefit payments will be made in advance of the actual planting. The amounts of such payments will be determined by the county association, subject to the approval of the Agricultural Adjustment Administration.

Producers must apply for membership in the county associations and must offer to enter into acreage-restriction contracts. Membership will run for 2 years and will obligate members to comply with any requirements which the Secretary of Agriculture may make as to acreage reduction or crop production for 1934 and 1935. Regulations for 1935 will not require an acreage reduction exceeding 25 percent of the 5-year average and will allow compensation on the same basis as for 1934.

Benefit payments on domestic allotments will be made, not on the total acreage planted but on the production for domestic consumption. In the 5-year period ended July 31, 1933, the average annual domestic consumption of cotton was approximately 5,565,000 bales. This quantity of cotton, allocated to the counties and thereafter to the individual producers ratably, establishes the basis for the payments.

If the price for the season plus the rental for the land taken out of production fails to bring the farmer's income from his share of the domestic consumption up to the parity price, he will receive a supplementary cash benefit tending to make up the difference.

WHEAT-ACREAGE REDUCTION

As previously noted, the wheat producers of the United States faced a gloomy situation in the early days of 1933. This country had accumulated since 1928 a supply of wheat from 125 million to 260 million bushels above its normal supply. This surplus constituted more than half the world's surplus of wheat. It disrupted and disorganized the wheat-price structure and impelled foreign countries to impose trade restrictions as a protection to their own growers. Our wheat carry-over at the end of the crop year 1932-33 reached the record figure of 363 million bushels. The foreign market had practically vanished. These circumstances forced down the price of wheat, which on January last averaged 31.6 cents a bushel at the farm. In the 5-year period August 1909 to July 1914, wheat in this country averaged 88.4 cents a bushel at the farm. Wheat prices early this year were far out of line with the prices of goods that farmers buy, and debts and taxes remained as high as when wheat brought three times as much per bushel.

To correct this situation the Agricultural Adjustment Administration put into effect a plan for reducing our wheat production. Its fundamental purpose was to enable each cooperating grower to shift his production to a lower level and to finance him in some measure while making the change. Specifically, the program provided for adjustment payments to each cooperating producer based on his proportionate share of the domestically consumed part of our wheat crop. This proportionate share became known as the farm allotment. It bore the same proportion to the total domestic consumption that the farmer's average 3-year production bore to the average total 3-year production of the United States during the period 1930-32.

In return the producer agreed to reduce his acreage for the 1934 and 1935 crop years. It was stipulated that the reduction required should not exceed 20 percent of the farmer's acreage. Subsequently the Adjustment Administration fixed 15 percent as the required reduction for the current crop year. In putting the program into effect the Administration offered contracts to 1,200,000 individual farmers in 40 States and more than 2,000 counties. It arranged for the organization of county associations to administer the program locally. The Department's Extension Service conducted an educational campaign among farmers, and helped to organize the county associations. Committees of these associations checked, corrected,

and approved farmers' reports of production and acreage and determined the individual allotments. The associations helped greatly to reduce the cost of administering the acreage-reduction plan.

Response of the Wheat Industry

Wheat producers generally recognized the soundness of the principles involved. They recalled that previous attempts at controlling production had broken down because the participants had no advantage over nonparticipants, but on the contrary suffered a disadvantage. Their action improved the market for outsiders who rushed into it sometimes with an increased volume of production. Farm organizations emphasized this fact at a hearing held in Washington on May 26 and urged wheat adjustment on the basis of individual allotments. Grain-handling agencies for the most part supported the proposal.

Reports are not yet complete as to the number of cooperating farmers. If all wheat farmers sign up, approximately \$120,000,000 will be paid to them, two thirds this autumn and one third after spring planting next year.

The cooperation of all the eligible farmers would mean, with the 15-percent reduction in their individual acreage, a total reduction of 9,600,000 acres. On the basis of average yields, this would reduce production about 124,000,000 bushels.

As provided in the Agricultural Adjustment Act the Administration imposed a tax on wheat processed for human consumption, to provide funds for the reduction program. The tax, which was fixed at 30 cents a bushel, was proclaimed June 26, 1933. The amount of wheat on which the processing tax will be paid was estimated at 460,000,000 bushels, or slightly more than 54 percent of our average wheat production in the 5-year period 1928-32. The payments to farmers for the crop year 1933 were fixed at 28 to 30 cents a bushel. The Administration estimated that 515,000,000 bushels of wheat would be used for human food during the year. The Agricultural Adjustment Act exempts from the tax all wheat processed by or for the producers. This quantity was estimated at 30,000,000 bushels. There was a further exemption from the tax of 25,000,000 bushels of wheat for use, in the form of flour, by charitable organizations. These exemptions left 460,000,000 bushels net as the amount on which the processing tax will be paid.

Wheat prices and also the prices of flour and bread rose after the imposition of the tax. Some persons contended that increases resulted exclusively from the processing tax. This was obviously incorrect. Wheat damage developed about the time the tax was imposed, and there was much talk of inflation. A major speculation movement took place. For a short time May wheat options in Chicago reached almost the pre-war parity. Subsequently, the speculation flurry subsided and prices declined. The whole movement, however, obscured whatever effect the processing tax may have had upon the price of wheat, flour, and bread. It is probable that the tax was responsible for an increase of only about one half cent per pound loaf of bread.

Provisions of the International Wheat Agreement

The general international wheat agreement among the importing and exporting countries signed by many of the countries at London, August 25, is conditional upon agreement by the four exporting countries as to restriction of their production and exports. A supplementary agreement between these four countries putting the principles into specific form has not yet been placed in final form and approved.

The most significant elements in the general agreement are:

1. The major wheat importing and exporting countries of the world face the facts of the world wheat problem and agree on a program of action to seek to correct them.

2. The exporting nations agree to control exports and to adjust production so as to help eliminate the excessive carry-over of wheat.

3. The wheat-importing countries agree to cease further efforts to expand their wheat production and agree to a policy of gradually removing tariffs and trade barriers as world wheat prices rise.

4. The countries participating in the conference will establish a joint committee to watch the working out of various steps. This international committee will meet from time to time and will be responsible for seeing that additional steps are properly taken.

The signing of the agreement by the importing countries is a significant step toward effective world cooperation in correcting the wheat surplus. It binds them not to take advantage of any efforts that the exporting countries may take to eliminate the excess supplies, but instead to adjust the policies of the importing countries so as to assist in correcting the situation as rapidly as possible.

The importing countries bind themselves (1) not to encourage further increase in their wheat acreages, (2) to attempt to secure increased consumption of wheat and to remove gradually the measures now lowering the quality of bread, which measures have tended to reduce wheat consumption, (3) to make a start in reducing the wheat tariffs after the world level of wheat has advanced to a point agreed upon, and (4) to modify their other restrictions such as import quotas, milling restrictions, etc., during the 1934-35 marketing season, even if they cannot do so during the current marketing season. This latter commitment is also conditioned on improvement in the world level of wheat prices.

While the commitment on the part of the importing countries to lower their tariff after wheat prices start rising may have little significance at the moment, it may become of very great importance in succeeding years. Obviously, the nearer that the world level of wheat prices approaches the wheat prices which prevail within the importing countries, the less need there will be for milling quotas, import restrictions, etc., and the easier it will be for the importing countries to carry through their commitment for the gradual abolition of these restrictions.

Landmark in International Effort

When the wheat agreement is finally concluded it will be a landmark in international efforts to solve the economic depression. Through it both the importing and exporting countries face the basic facts which have caused the abnormally low world wheat price and agree to take definite steps to correct that situation. Prices are

only symptoms; production, supplies, and consumption are the underlying factors which prices reflect.

For the past 10 years the wheat countries of the world have been following irrational policies. The exporting countries have been maintaining or increasing production in the face of diminishing markets. The importing countries have been taking steps that resulted in encouraging their farmers to expand their production of wheat, even on high-cost land, in spite of the fact that wheat could be bought for very low prices in world markets. Low prices in importing countries have not restricted production. Low prices in world markets have been accompanied by restrictive measures and falling consumption in importing countries. Now all important wheat countries face these facts and agree that the future must be different. The next 5 years may see striking progress in straightening out the difficulties which the previous irrational policies produced.

The work done on the international agreement was made possible by the Agricultural Adjustment Act. In the form it has now reached, the agreement constitutes a courageous effort to face the facts of recurrent world surpluses of wheat and to grapple intelligently with the fundamentals involved. It is an effort to break the vicious cycle of surpluses, excessive tariffs, ruinous prices, economic paralysis, and bread lines in this and other countries. This Nation took the lead early last spring in initiating steps which led to summoning the conference. The State Department worked in closest cooperation with the Department of Agriculture throughout the negotiations. Premier Bennett of Canada supported the United States in getting the exporting countries to reach an understanding on principles.

Outlook for 1934 and 1935

Two factors enter into our situation as it may develop in 1934 and 1935. Neither concerns the possibility of an enlarged foreign market, which possibility depends on purchasing power abroad as well as on the wheat-price level. These two factors are (1) the actual acreage reduction, and (2) the prospective production on the reduced acreage. The year 1933 was a year of drought and low wheat yields. Winter wheat yielded only 12.7 bushels per acre and spring wheat 9.2 bushels. The average on the entire wheat acreage was 11.3 bushels, the lowest in 40 years. Total production was 506,557,000 bushels, according to the October crop report. It is usual for yields to be high following years of drought. Favorable weather conditions in 1934 may partly offset the acreage reduction, and the Nation may again face an increase in wheat supplies. In that case prices will be likely to fall, and it may be necessary to ask, under the farmers' contracts, for an acreage reduction to the full amount of the permissible 20 percent.

Another short crop year would create an opposite situation. Wheat might rise to the parity price. Such a rise would obviate the need to make adjustment payments and would warrant dispensing with an acreage reduction or requiring only a small reduction. The wheat program is flexible enough to meet a big-crop or a short-crop situation. Wheat growers who cooperate in it will have, whether the crop be large or small, a return approaching the parity price for at least part of their production.

The wheat contract binds each man who signs it to use the land taken out of wheat in such a way that it will not add to the surplus of any nationally produced agricultural product for sale. This requirement creates a problem of alternative uses for the displaced land. The contract permits this land to be summer-fallowed, to be planted to soil-improving or erosion-preventing crops, to food crops for home consumption on the farm, or to crops for the production of livestock (or livestock products) for home consumption or use on the farm.

It is extremely important to prevent erosion on the acreage removed from wheat production and to keep out noxious weeds. Pastures are one of the most satisfactory replacement crops. Grasses give good cover to the land, prevent erosion and weed growth, and ordinarily do not increase damaging surpluses of commodities nationally sold. The land-use policy cannot yet be considered fixed. Dairy and livestock farmers have an interest in the uses made of the wheat land withdrawn from wheat. It is important not to increase the commercial production of milk or meat. Substituting pastures for wheat and corn, however, will reduce the total amount of feed available for the dairy, beef, and pork industries. Pasture offers a low-pressure method of producing milk and meat which may at this time be substituted for the high-pressure feeding method which this country developed during and after the war.

EMERGENCY HOG PROGRAM

Adjustments in hog production presented extremely difficult problems. The farm price of hogs, despite an advance of nearly 50 percent from the low point of last January, remained in August only about one half of the fair exchange value called for in the Agricultural Adjustment Act. On August 15, the farm price of hogs averaged only \$3.79 a hundred pounds, as compared with a pre-war average of \$7.47. Following a sharp decline in the market for speculative commodities came severe breaks in the prices of lard and dry-salt meats.

Excessive supplies during May, June, and July depressed the market in late summer. In these months the hogs slaughtered in Federally inspected plants numbered 2,750,000 more than in the corresponding months of the previous year. This was a 30-percent increase. The slaughter was about 5 percent greater than the previous record total for May, June, and July.

The movement of hog products into domestic consumption during the summer was only a little larger than in the summer of 1932. There was only a slight increase in exports. In consequence, the supply of hog products in storage increased greatly. Lard stocks on August 1 were 80 percent above those of the same date in 1932, and storage stocks of other pork products were 26 percent greater. The excessive storage stocks, hot weather in many sections, and continued heavy marketing, prevented the usual summer advance.

There was no prospect of quick improvement through the natural course of events. Supplies of hogs for market during the fall and winter seemed likely to be larger than those of a year ago. The June pig survey had indicated an increase of 13 percent in sows for fall farrowing in the Corn Belt. A sharp reduction in feed-

grain supplies later suggested that the fall farrowings would be less than the June survey indicated, but nevertheless as great or greater than those of 1932.

It seemed probable also that many unfinished cattle would enter the market in competition with hog products. An extreme shortage of feed in many areas foreshadowed large market supplies of grass-fed cattle from the Western States. Because of the small corn and feed crops in most Corn Belt States, the demand for grass-fed cattle to go into the feed lots was expected to be small.

In these circumstances hog farmers recommended and the Agricultural Adjustment Administration adopted an emergency program calling for the purchase of pigs and sows due to farrow. This program involved the purchase of slightly more than 6,000,000 pigs and lightweight hogs weighing from 25 to 100 pounds at prices well above the market.

For hogs about 100 pounds in weight, the price offered averaged about \$6 a hundredweight. For pigs weighing 25 pounds the prices ran as high as \$9.50 a hundredweight. For sows due to farrow weighing 240 pounds or more, the Administration offered a bounty of \$4 a head above the market price. It was arranged that these sows should not be subject to the usual dockage. Accordingly the actual premium per sow amounted to about \$5 a head.

Methods Used in Emergency Program

Packers purchased the pigs and sows for the account of the Department of Agriculture. At the above-mentioned prices the Administration accepted only pigs in good health and showing normal growth and no body deformities. Representatives of the Department inspected, at processing plants and public stockyards, the pigs and sows purchased under this program.

The Emergency Relief Administration purchased the meat at a price sufficient to defray the cost of processing, storage, and freight, and handled it so that it did not compete with commercial supplies.

Inedible pigs and sows, or animals which for various reasons could not practicably be used for human consumption, were as far as possible converted into salable inedible products such as grease, for which the best market prices were obtained. Wherever the price for such inedible products was so low as not to return the costs of conversion the material was dumped. Misinterpretation of this procedure, unfortunately, gave rise to rumors and press stories that human food was being wasted or dumped in the river.

To finance the undertaking the Administration arranged to collect a processing tax to average about 50 cents per hundredweight on all hogs marketed during the 1933-34 marketing season. It was estimated that the pig and sow purchases by the Administration would immediately add 30 to 35 million dollars to the income of the hog farmers. In addition, the diversion of these pigs and sows to noncompetitive edible uses and to nonedible products removed approximately one and one fifth billion pounds of hogs from the fall and winter supplies. This will result in higher hog prices through the 1933-34 hog-marketing year than would otherwise have obtained, especially from January through April.

Permanent Policy Necessary

It is necessary to follow the emergency hog-reduction plan with a more effective and permanent control. This should include corn production as well as hog production. Unless the corn acreage of the United States drops sufficiently to compensate for the reduction in hog production, the production of other kinds of livestock will be stimulated. Hog farmers moreover will be tempted to expand their operations. It is calculated that for each reduction of 10 head in the output of hogs, from 7 to 8 acres should be withdrawn from corn growing.

The excessive production of corn and hogs constitutes a problem requiring a unified program of control, which is nevertheless only part of a larger problem involving all the feed crops and all livestock production.

From approximately 100 million acres of land this country annually produces an average of 2,600,000,000 bushels of corn. This year's production, according to the September estimate, will be only 2,285,000,000 bushels from 103 million acres. The average wholesale slaughter of hogs is approximately 50 million head. Heretofore, the gross value of both corn and hogs was at a maximum when the production was 10 to 20 percent below normal. It would be desirable to reduce hog production by some 10 million head, and corn production by 350 to 500 million bushels.

A plan for reducing corn acreage by at least 20 percent and hog farrowing by at least 25 percent in 1934 has been launched. The plan involves a maximum of \$350,000,000 in benefit payments to farmers who participate. It was formulated after conferences with the National Corn-Hog Committee of Twenty-five, composed of producer representatives of 10 Middle Western States. Between 1½ and 2 million farmers in this country produce corn and hogs as a major enterprise. The majority of these are in Ohio, Indiana, Illinois, Missouri, Kansas, Nebraska, Iowa, South Dakota, Minnesota, and Wisconsin.

Payments to each farmer for corn reduction will be in the form of a rental at the rate of 30 cents per bushel on the average preceding 5-year production of the contracted acreage. Each participating farmer will receive adjustment payments of \$5 per head on the number of hogs, equivalent to 75 percent of the average annual number of hogs from home-farrowed litters sold by him during the last 2 years. Announcement of the corn-hog program for 1934 followed the completion of the emergency hog program.

To be most effective, any long-time program should deal with the feed crop-livestock situation as a whole. This is not possible under the present act. It is possible that the act may be amended later to include other livestock and feed crops as basic commodities so that a complete program can be put into effect.

DAIRY-INDUSTRY ADJUSTMENTS

In considering the adjustments that are being undertaken in the dairy industry it is quite important to have a broad picture of the production situation. The number of milk cows on farms in the United States reached an all-time record in January 1933. The

number of calves and heifers kept on farms for future milk production was likewise at or near an all-time peak. The pastures, forage crops, and concentrates with which to feed this mammoth dairy herd were temporarily restricted by the severe and prolonged drought which prevailed over wide production areas. Consumer purchasing power is not sufficiently large to absorb at satisfactory prices to farmers the huge quantity of dairy products these cows are capable of producing under more liberal feed conditions. These simple facts show plainly that many of the present troubles were already in the making before the Agricultural Adjustment Act came into being.

The number of milk cows was increasing more rapidly in the West North Central States and in the South Central States, where wheat, corn, and cotton predominate, than in any other section of the United States. The increase in numbers of milk cows for these two regions for the 1929-32 period was fully 10 percent. An important reason for this increase is found in the changes in the butterfat-feed price ratio. During the pre-war period, and even up to 1920, 1 pound of butterfat would buy approximately 20 pounds of grain on an average farm in the United States. During the postwar decade, 1 pound of butterfat would purchase about 30 pounds of grain. In December 1932 the same amount of butterfat would buy nearly 60 pounds of grain. In the West Central States this relationship reached a point at which 1 pound of butterfat would purchase approximately 75 pounds of grain, even though both grain and dairy prices were undesirably low. Fully 40,000,000 acres were formerly used for the production of grains and cotton for export markets to which trade channels have been obstructed by tariffs, import quotas, and other trade barriers. Naturally there was a tendency to use these acres for the production of products for domestic use and for which prices were relatively more favorable.

The problem of improving and maintaining the purchasing power of dairymen had two major angles. The first was to curb the former trend toward dairying, and the second was to bring about a satisfactory adjustment within the industry itself. The proper place to start was naturally to raise wheat and cotton prices and thus give these farmers an opportunity to make a living without becoming commercial dairymen. The increase in grain prices in the summer of 1933 caused the butterfat-feed ratio to drop to its pre-war level, making dairy farming less inviting. For the dairy farmer producing his own feed this merely meant that more of his income might be attributed to the production of feed and less to the conversion of these feeds into dairy products. The net result is no material change in his total income. The dairyman who buys a large part of his feed and who has found the higher feed cost burdensome should remember that higher feed costs will eventually mean less excess production and higher prices for dairy products.

Measures Being Developed

Measures that are being developed under the Agricultural Adjustment Act to improve conditions within the industry can be grouped into three classes: (1) Marketing or trade agreements, (2) purchasing operations, and (3) production control.

Practically every branch of the dairy industry has a trade agreement of some kind under consideration. Fluid-milk agreements are

the most numerous. These agreements are voluntary. However, they apply to both contracting and noncontracting producers and distributors through a blanket licensing provision covering all distributors of milk and cream in the sales areas. These agreements establish prices to producers for milk used for sale as fluid milk and cream and provide the basis upon which additional or surplus milk may be purchased from producers. The wholesale and retail prices are usually specified, or at least some limitations are placed on the maximum and minimum prices that may be charged consumers. Each agreement contains a code of fair practices which agencies in the market must observe. Chicago, Philadelphia, Detroit, and Minneapolis and St. Paul were among the first markets to obtain agreements of this kind. The producers' associations, distributors, and the Secretary of Agriculture are parties to these fluid-milk agreements.

National agreements are in effect for dry skim milk and for evaporated milk. Agreements for these products do not go as far in regulating prices as those for fluid-milk markets. The evaporated-milk agreement establishes the basis for the purchase of milk used for manufacture into evaporated milk, but it does not cover milk used by these same plants for other purposes. The dry-skim-milk agreement does not attempt to regulate prices beyond the limitations of discounts and commissions on certain types of sales.

A national agreement for frozen desserts (ice cream) has been considered at a public hearing and is being redrafted preparatory to its submittal to manufacturers and distributors for signature. This agreement will be supplemented with affiliated or sectional agreements which are expected to establish minimum prices to producers.

A national butter agreement is in its final state of preparation. Like the agreement for dry skim milk, it attempts very little in actual price regulation, but prescribes the methods that will cover the procurement of butterfat, as well as the distribution and sale of the butter manufactured therefrom.

After many conferences a tentative cheese agreement was prepared by representatives of various parts of the industry. The proposed cheese agreement contains the unique feature of providing for price committees to replace the present cheese boards and exchanges.

Government Purchases of Butter

During the summer of 1933 the Agricultural Adjustment Administration acted to strengthen butter prices by arranging for the purchase and removal from the market of considerable quantities of butter for distribution to the unemployed through the Surplus Relief Corporation. Consumption through the regular channels of trade, however, was not increased, and cold-storage holdings mounted. As heavy production continued it became apparent that the purchase of butter for relief purposes was not sufficient to maintain a steady market as long as production continued to exceed consumption. The removal of some butter from the commercial market was helpful temporarily, but the inadequacy of such action emphasized the necessity of developing an effective production-control plan that would hold the output of dairy products down to the amount that would be consumed at a fair price to producers. Revenue for

the removal of surplus dairy products from the market and for making benefit payments to producers in connection with the program for production control was provided for by the application of a processing tax on dairy products.

The most fundamental problem that the dairy industry has before it is that of adjusting production to a point where consumers will absorb at reasonably satisfactory prices to producers the quantity of dairy products placed on the market. This will necessitate the development of one of the most important production-control plans in the entire agricultural industry.

If production should continue to increase, very serious damage might be done to the entire dairy industry. Milk production is on a domestic basis by a very slight margin. While it will probably remain on a domestic basis, yet every increase in dairy output will result in lower prices relative to prices prevailing in foreign markets. Our butter prices, low as they are, are still above the prices of butter in Copenhagen, London, and other world markets by a sizeable margin. This situation emphasizes the necessity of controlling dairy surpluses at their source.

No degree of agitation against butter substitutes will be sufficient to turn the tide. Price raising by use of the processing tax or through marketing agreements will likely prove quite unsatisfactory to producers unless accompanied by a production-control plan. Dairy producers have no alternative except to adjust their production if they are to place themselves in a position where prices for dairy products will continue at reasonably satisfactory levels.

Excessive Distribution Charges

Dairy producers have the opportunity of placing the processing and distribution of their products on a more efficient and satisfactory basis than exists at the present time. Public hearings and investigations have revealed instances of excessive distribution charges, collusion of producers and distributors, control from superorganizations, and even "rackets" of one form or another.

Large dairy corporations have not shared with the producers and consumers the major advantages that they have had from large-scale operation and resulting lower operating costs. These advantages instead have been reflected in large executive salaries and in liberal stock dividends on capitalizations that too frequently do not rest upon intrinsic values in plant and equipment. Producers' associations, particularly in fluid-milk markets, have frequently sought market advantages for their members by entering into agreements with distributors on a basis that restricted marketing opportunities to their own members and protected distributors' profits. Such action results in higher prices to consumers in these areas and in limited opportunities for the remainder of the dairy industry. If producers' associations are to retain the full support of their members they will need to give more attention to the opportunities that exist for economies in distribution and for adjustments in charges from the farms of producers to the homes of consumers.

The threat that faces new agencies in many milk markets, the destruction of dairy plants by bombing and other means, the concessions that must be made for the privilege of selling milk in many

apartment houses, are all evidences of undesirable forces at work in the distribution of milk and its products. More aggressive action is necessary to rid the industry of these undesirable elements. The Department of Agriculture, through the new powers granted it under the Agricultural Adjustment Act, is desirous of assisting the dairy industry to adjust itself to new economic conditions and to place the processing and distribution of its products on a basis that will invite the full confidence of the general public.

REDUCING TOBACCO PRODUCTION

In considering the application of the Agricultural Adjustment Act to tobacco it is necessary to recognize that there are a number of very different kinds of tobacco. Altogether 25 distinct types, produced wholly within the United States, are recognized in the official classification of the Department of Agriculture. Differences between types are due largely to the varieties of seed, climate, and methods of curing. Some of the types have similar characteristics and uses. They are grouped by the Department into the following classes: (1) Flue-cured, (2) dark fire-cured, (3a) light air-cured, (3b) dark air-cured, (4) cigar binder, (5) cigar filler, and (6) cigar wrapper.

All the types except burley (light air-cured) and the cigar types have important export outlets, and most of them are used in several different products. For consumption in the United States, the cigar types are used in cigars and scrap chewing tobacco; burley and the flue-cured types are used in cigarettes, smoking mixtures, and chewing tobacco; the fire-cured types are used in snuff and in certain classes of cigars; the dark air-cured types are used in chewing tobacco and smoking mixtures. Most brands of products utilize several different types of tobacco; consequently there is a certain amount of competition between types.

It is perfectly natural that the existing situation with respect to the principal types of tobacco should present a complex picture. Inevitably, the changing modes of world consumption, the unfavorable influence of trade restrictions, and the increasing competition of foreign-grown tobacco have been reflected on producers of the different types in the United States with varying degrees of intensity. Prices for nearly all types reached record low levels in the crop year 1931-32, following which material reductions were made in the 1932 acreage. In the crop year 1932-33 prices of burley and the flue-cured types showed considerable improvement, prices of other non-cigar types also increased slightly, but prices of the cigar types declined to new low levels.

Difficulties Most Acute With Cigar Types

In applying the provisions of the Agricultural Adjustment Act to tobacco it was decided to begin with the cigar types. This decision was based largely on the fact that growers of these types were suffering more acutely from the accumulation of surplus than the growers of any other types. To this was added the further consideration that, at the time the Tobacco Section of the Agricultural Adjustment Administration was created, the planting of the 1933 crop of cigar tobacco was not as far advanced as the planting of other

tobacco; consequently, it was believed that a plan for acreage reduction in 1933 could be put into operation more effectively for the cigar types.

Production of the cigar types ordinarily represents about 10 to 12 percent of the United States production of all types. It is used almost exclusively for domestic consumption. Briefly, the situation with respect to these types was as follows: (1) Cigar consumption has been declining over a period of 12 years; during the past 4 years it has declined 40 percent; (2) production of the cigar types has exceeded consumption for several years; (3) less than half the farmers had been able to sell their 1932 crops, and prices for the crops sold were about 50 percent below fair exchange values as defined in the Agricultural Adjustment Act; (4) surplus stocks had accumulated all the way from the producer to the manufacturer (at the current rate of consumption, if no cigar tobacco was grown in 1933 and 1934, there would be at the end of the 2 years but few grades of which there would be a shortage); and (5) stocks of the lower grades were larger than stocks of the better grades.

The Administration began by consulting with representatives of all branches of the cigar industry. Conferences were held with economists from the agricultural colleges of States in which the cigar types are produced, with growers and growers' representatives, and with leading dealers and manufacturers. Early in these discussions it became evident that it would be necessary (1) to define all cigar types of tobacco together (filler, binder, and wrapper) as a basic agricultural commodity, (2) to apply a processing tax to this commodity for raising revenues with which to reduce supplies, and (3) to extend the program for reduction over a 3-year period. Proposals recommended to the Administration for adoption included acreage reduction, combined with benefit payments; the removing from commercial uses of surplus farm stocks, combined with benefit payments; and marketing agreements, both with and without the licensing of buyers and establishment of minimum prices.

Projects Affecting the Cigar Types in 1933

Two projects were definitely undertaken to reduce the size of the 1933 crop of cigar tobacco, the most extensive of which related to the four districts producing the filler and binder types. It provided for reducing the acreage harvested in 1933 to approximately half that grown in 1932, and limiting the acreage in 1934 and 1935 to the same extent, or by a lesser amount, at the discretion of the Secretary of Agriculture. About 18,000 growers, or approximately 70 percent of the total number in the United States, participated in the program in 1933, and it is estimated that production was reduced about 18,000,000 pounds, or 20 percent, below what it would have been otherwise. Estimated payments to growers total about \$2,500,000.

The project dealing with the wrapper type of cigar tobacco grown in Georgia and Florida provided for making payments to growers for leaving unharvested in 1933 an average of four top-stalk leaves, approximately one fifth of the total number of leaves per plant. Ninety-five percent of the growers participated in this project, as a result of which production was reduced about 350,000

pounds, or 23 percent, below what it would have been. Estimated payments to growers total approximately \$85,000.

For Connecticut Valley shade-grown tobacco, a marketing agreement has been entered into between the "handlers" and the Secretary of Agriculture for the purpose of regulating the quantity of that type of tobacco entering interstate commerce. Owing to the limited outlet for cigar-wrapper tobacco, on the one hand, and the heavy investment required for production, on the other, the Connecticut Valley shade-grown industry includes less than 50 producing units. All the handlers, except one, are also producers. Thus, an agreement of this kind is peculiarly adaptable to the industry. In contrast with most agricultural products, the problem of control is relatively simple, and the coordination of group interests is not so difficult.

The agreement does not affect the quantity of the 1933 crop going into interstate commerce, as that crop was nearing maturity when negotiations were started. But for the crop of each subsequent year (until the agreement is terminated), the quantity permitted to enter interstate commerce, and therefore the quantity produced, may be limited, subject to approval by the Secretary of Agriculture. All the tobacco including the 1933 crop shall be graded according to United States standard grades and, subject to the Secretary's approval, minimum prices may be established on each grade.

Initiating the Cigar-Leaf Program

In initiating the program for the cigar types the Administration encountered but few difficulties. To most persons the purposes were obvious, and the need was so great that all branches of the industry willingly gave their cooperation. However, with the limited time available for educational work it was inevitable that some misunderstandings should occur.

Perhaps the most difficult thing for the farmers to understand was why they should be limited in the use of the land on which payments were made. At the time the plan was announced a considerable cut had already been made in the 1933 tobacco acreage, and other crops had been planted on the land taken out of tobacco. An acute feed shortage threatened in some sections. We were aware of this and agreed that in 1933 half the contracted acreage could be used for crops to be consumed directly or indirectly on the farm, without influencing the amount received in payments. Also, the grower was given the alternative of using all the contracted acreage for such crops and accepting appropriate reductions in payments. But, inasmuch as one of the primary purposes of the Administration was to retire land from production, it was obviously undesirable to make full payments to the grower and allow him to use all the land for other crops.

Another difficulty related to the base tobacco acreage. It was provided in the contract that no producer could grow an acreage of tobacco greater than 50 percent of his base acreage, although each had the opportunity of choosing one of three methods for determining that base. Since in any given district the amount of money received in payments was determined largely by the number of acres in the base tobacco acreage, many growers tried to obtain the

highest possible base, perhaps not realizing that to obtain the payments would require that restrictions be placed upon the use of the land.

Our view was that in making additional adjustments of acreage in 1933, account should be taken of the adjustments already made. For this reason, the acreage planted in 1931 and 1932 was used in determining the base. If a grower had already reduced acreage before 1933, it was assumed that other enterprises had been found to substitute for tobacco; and if the acreage had not been reduced, it was assumed that no such enterprises had been found. No doubt some growers adjusted acreage in an effort to help improve the tobacco-supply situation, but probably most of them had in mind improving their own financial position.

Meeting the Flue-Cured Situation

For flue-cured tobacco, the situation differed materially from that of the cigar types, (1) because supplies were not so excessive, and (2) because exports represent so large a part of the production (around 60 percent). Owing to the more favorable supply situation, the possibilities for immediate improvement of prices were greater, but from the standpoint of total income to growers, there was danger that too large a curtailment of production would decrease income rather than increase it. Foreign production of flue-cured tobacco has expanded rapidly in recent years, and high prices in the United States will tend to increase foreign displacements.

Prior to the opening of markets for the 1933 crop, preliminary discussions were held both with growers and manufacturers. At that time it appeared that the 1933 crop would be no larger than annual consumption, and the principal buyers expressed the belief that fair prices would be paid for this crop. The July 1 forecast was for a production of 591,159,000 pounds but as the season progressed it became evident that the favorable growing conditions would result in a much larger crop (estimated in October at 705,103,000 pounds). When the markets opened in Georgia on August 1 growers expressed considerable dissatisfaction with prices, and as the prospects for production improved prices weakened. Finally, when the eastern North Carolina markets opened (Aug. 29) at levels lower than had prevailed in Georgia and South Carolina, the dissatisfaction became so great that on September 1 all the markets were closed at the request of the Governors of North Carolina and South Carolina.

During this emergency 95 percent of the growers signed contracts with the Agricultural Adjustment Administration agreeing to reduce their production in 1934 and 1935 by an amount requested by the Secretary of Agriculture not to exceed 30 per cent of the average 1931-33 production. Simultaneously, a marketing agreement was entered into with the large domestic manufacturers using more than 90 percent of the flue-cured tobacco manufactured in the United States, to establish an average minimum price (17 cents per pound) for a quantity at least equal to the quantity which they used during the last fiscal year (about 250,000,000 pounds). They had already purchased this season about 75,000,000 pounds in addition to the quantity included in the agreement.

The markets reopened September 25 with prices at materially higher levels. Buyers for export were not included in the agreement, but they increased their prices along with the domestic buyers. If the prices now prevailing (Nov. 3) continue throughout the remainder of the season, the farmers' income from the 1933 flue-cured crop will be about two and one half times the income from the small 1932 crop. The purchasing power of the 1933 crop in terms of commodities farmers buy will be greater than that of any of the last 4 years and greater than the average for the 10-year period 1919-28. In addition to the increased income from the 1933 crop, farmers who participate in the reduction program in 1934 will receive cash payments aggregating around \$17,000,000, almost \$10,000,000 of which will be in the present marketing year.

Other Kinds of Tobacco

Arrangements are going forward for the adjustment of supplies with respect to the other kinds of tobacco in the United States. Burley, Maryland, fire-cured, and dark air-cured tobacco, each has been defined separately as a basic agricultural commodity. These, together with flue-cured and the cigar types, comprise all the domestic types of tobacco. A separate program is being developed for each. In general, the problem is that of reducing production to bring supplies into line with consumption. The surplus is greatest in the case of burley, although supplies are above normal for each kind of tobacco.

The total production of tobacco in the United States in 1933 (all types combined) was estimated in October at 1,413,000,000 pounds. This is approximately 200,000,000 pounds above the world consumption estimated for these types, whereas the small 1932 crop of 1,016,000,000 pounds was about 200,000,000 pounds below world consumption. The carry-over of tobacco in the United States on July 1, 1933, was 2,000,000,000 pounds, which was second only to the record carry-over of 1932 and 20 percent above the 5-year average, 1927-31, when consumption was somewhat larger than at present.

Taxing the Processing of Tobacco

Processing taxes, effective October 1, have been placed on all kinds of leaf tobacco. The rates per pound of such taxes (farm-sales weight) are as follows: Cigar leaf, 3 cents; flue-cured, 4.2 cents; burley, 2 cents; Maryland, 1.7 cents; fire-cured, 2.9 cents; and dark air-cured, 3.3 cents.

The problems relating to the taxation of tobacco are complex. Notwithstanding the fact that tobacco products have long been subject to internal-revenue taxes, the levying of processing taxes raises questions involving both the equivalence and equities of tax rates.

The particular tobacco on which processing taxes are levied is taken from storage and not the tobacco on which price differentials, or fair-exchange allowances, are established. Seldom will it be found that the quality of crops and farm prices of tobacco removed from storage will be the same as the quality and farm price of the current crop. Also, during the period of aging and fermentation tobacco undergoes losses of weight amounting to as much as 20 percent

of farmers' selling weights. Thus the differences of weight have to be taken into account in making the tax levy.

The application of a given rate of tax uniformly over all grades and qualities of a given kind of tobacco, on some of which farm prices regularly vary several hundred percent, may cause shifts in the consumption of these grades and qualities. Furthermore, in taxing one kind of tobacco at one rate and other kinds at different rates there is danger that competitive relationships between types may be disturbed. In dealing with all these problems the Administration will need to proceed carefully and cautiously. If it is found that, as a result of a particular taxing program, shifts in consumption are taking place, the policy will be to take such steps as may be necessary to correct the situation.

FRUIT AND VEGETABLE AGREEMENTS

In the fruit and vegetable field, the problem of adjusting supplies to effective market demand is fourfold. It is necessary (1) to prevent excessive supplies at the height of the marketing season from flooding the market and seriously depressing prices, (2) to restrict market offerings during entire seasons of large production, (3) to regulate the flow of supply to various consuming markets so as to prevent local gluts and shortages, and (4) to control long-time tendencies toward increased production.

These four aspects have long been recognized, and various attempts have been made by cooperative marketing organizations and other groups to solve them. In a number of States, clearing-house and voluntary pro rata plans have been tried. During seasons of surplus production these have been utilized to limit the flow of supply to market. Shipments have been prorated among the various shippers, who in turn have prorated salable quantities among the various growers for whom they market. In some instances these plans have received wide support, as many as 80 or 90 percent of the growers of a given commodity participating in them. But they have had the serious weakness of permitting the growers and shippers who do not participate to profit by the action of those who do. This in turn tends to cause the participants to become dissatisfied and to break down the whole arrangement.

Attempts have been made to bolster up this weakness through the passage of State pro rata laws. Such a law was recently enacted in California. Sponsors of these laws have recognized that they could be really effective only in the few instances where a single State controlled the entire supply during the marketing season.

The Agricultural Adjustment Act opened the way for the first time to make the pro rata plans fully effective. The portions of the act providing for marketing agreements covering the various agricultural commodities and the licensing of all the dealers or processors handling these commodities made it possible to bring about complete unanimity of action. Since fruits and vegetables were not included as basic commodities under the act, funds for production-control plans could not be obtained through any processing tax, and the only method by which supply could be controlled was through the marketing agreements and licensing.

Cling-Peach Agreement

The first marketing agreement to be formally approved covered the California cling-peach industry. More than 99 percent of the output of canned cling peaches is produced in California. Thus it was possible to achieve complete control of the situation through the one agreement. The total peach pack was limited by agreement to 218,000 tons, or 10,000,000 cases. In the event that the supply of No. 1 cling peaches exceeded this amount, the pack was to be allocated among the canners through an allocation board. In case the supply was less than 218,000 tons, enough No. 2 peaches to make up the difference were to be canned.

From the growers' standpoint, the most important feature of the agreement was that it guaranteed them a price of \$20 a ton for their harvested fruit and an equivalent amount for that which was not harvested. Another feature was the setting of minimum and maximum prices, varying according to grade and classification, at which the canners might sell their peach pack. Funds for the purchase of the surplus crop were to be obtained from payments by the canners of \$2.50 or more per ton for each ton of peaches they packed. Administration of the agreement was to be under the direction of a control committee of 10, representing growers, canners, and the consuming public.

Formulation of other marketing agreements, calculated to meet situations where the commodity is not canned but goes directly into consuming channels, followed approval of the peach agreement. One of these dealt with California deciduous tree fruits; another with apples and other tree fruits produced in Washington, Oregon, Idaho, and Montana; a third with California Flame Tokay grapes; and others with the citrus industry of California, Arizona, Texas, Florida, and Puerto Rico.

Each of these proposed agreements was intended to set up the machinery for the operation of pro rata plans under official supervision, with equitable treatment of the shippers and growers in the several shipping districts, so that all would contribute to the success of the plan by withholding a portion of their shipments when necessary.

The three citrus agreements, affecting the California-Arizona, Texas, and Florida producing areas, contained an identical section providing for a national stabilization plan, through the creation of two National Citrus Stabilization Committees—one for oranges and one for grapefruit. This plan was intended, in seasons of excessive production, to make possible the limitation of the total volume of supply going into market channels in the United States and Canada, and the prorating of this supply in an equitable manner among the various producing areas.

Other agreements were in process of formulation for other fruits and vegetables and the various nut crops.

The problem of controlling the prices of eggs and poultry is extremely complex. These commodities are produced on 5,400,000 of the 6,000,000 farms in the United States and are sold to millions of buyers. Another complicating factor is the cold-storage holdings of poultry and eggs. As in the case of fruits and vegetables, it is not possible to use a processing tax to finance a production-control campaign.

Series of Agreements Contemplated

Accordingly, the Administration seeks to complete a series of marketing agreements framed and coordinated so as to bring order into the production and marketing of fruits, vegetables, nuts, and other products. These agreements, integrated into a component whole, would (1) prevent seasonal surpluses from demoralizing the market, (2) level the flow of supply to market during the producing season, and (3) coordinate shipments so as to keep them rolling toward the various terminal markets as fast as, and no faster than, needed.

The benefits to the producer in the way of increased prices from such a coordinated system promise to be large. The costs of packing, transportation, and marketing are virtually fixed charges, and unless the selling price exceeds this amount, the grower gets nothing. Therefore a small increase in the selling price in the market may result in a substantial increase to the grower. This increase, even if passed on to the consumer in full, would mean only a small percentage increase in the retail price.

Actually, important benefits are promised for the consumer also. A well-integrated marketing system, assuring an adequate supply and preventing so far as possible the alternating gluts and shortages that now frequently occur, means that fruits and vegetables will reach the consumer in better condition.

Fruit and Vegetable Situation Better

The economic position of fruit and vegetable growers in the United States as a whole is much improved over that of last year and even that of 1931. After 3 years of declining prices and sharply reduced incomes, the producers of these commodities are experiencing a reversal of the trend this year and are receiving much more satisfactory returns.

Preliminary estimates of gross income from all fruits and vegetables indicate that the 1933 total is likely to be about one half again as large as that of 1932, about one sixth larger than the income in 1931, and only about one tenth smaller than that of 1930. Gross income from fruit and truck crops is about one fourth greater than in 1932, while that from potatoes may be about trebled and from sweetpotatoes almost doubled.

A combination of circumstances has contributed to these larger incomes this year: (1) The planted acreages of many vegetables were reduced slightly—a reversal of the tendency to expand gradually in recent years; (2) unfavorable weather conditions greatly reduced yields in many of the growing areas of both vegetable and fruit crops; and (3) there has been some improvement in demand conditions, owing to an increase in employment and to a rise in wages.

As compared with 1932, the acreage of potatoes was reduced about 4½ percent, sweetpotatoes 12 percent, and all other vegetables for fresh-market shipment about 8 percent. Of course, the acreages devoted to fruit crops remained practically the same as in 1932.

While producers have made an effort to bring the production of vegetables in line with existing market demand, untoward weather conditions this season have reduced yields of both vegetable and fruit

crops in many areas. The effect of these weather factors probably has done more toward balancing supply with demand than the efforts to reduce planted acreages. Drought and high temperatures in the Central States and surrounding sections reduced yields sharply.

The Season's Production

Production of all fruits together this year is approximately 2 percent below that of 1932, which was about an average crop. Production of apples, peaches, and prunes is slightly larger than last year but less than the average, while that of pears and grapes is smaller. Production of all fruits, excluding citrus, is about 12 percent below average. Citrus crops probably will be slightly smaller than last year, but about 25 percent greater than the 1924-29 average. Two hurricanes, one striking Florida and the other southern Texas during the first week of September, did considerable damage to the citrus crops in those areas. The Texas grapefruit crop was practically wiped out.

The potato crop this year is the smallest since 1925, or about 50,000,000 bushels below that of 1932, which was an average crop. Sweetpotato production is about 9,000,000 bushels lighter than that of last year, but about 6,500,000 bushels above the average.

Production of commercial vegetables for fresh-market shipment (excluding potatoes and sweetpotatoes) is about 9 percent below that of last season and about 2 percent below the average of the 5 previous seasons, while production of vegetables for canning is about the same as a year ago but nearly 30 percent below the average production of the previous 5 years. Of the vegetables for fresh-market shipment this year, the September estimates indicated that onions are reduced about 23 percent compared with the 1932 crop; cabbage is reduced 21 percent; cauliflower, 9 percent; tomatoes, 8 percent; snap beans, 7 percent; and lettuce, 6 percent. There were some increases. The production of fresh peas was increased 23 percent and spinach 6 percent over these crops of last year.

With the shorter supplies available for market and with improvement over last season in the demand situation, prices of most fruits and vegetables are higher than they were in 1932. Fruit prices in general are up about 20 percent; potato prices are from two to three times those of last year, and there has been some advance in prices of most of the vegetables for fresh-market shipment. Most of this advance has come in the latter half of the season, at the beginning of which it became known that short crops of the major fruits and vegetables were in prospect. Also it was not until near the middle of the year that employment and pay rolls had made appreciable gains and commodity prices in general began to rise.

SPECULATION IN COMMODITIES

Speculation on the commodity exchanges handicapped the agricultural recovery program during the summer. Temporarily it pushed prices out of line with supply and demand conditions to such an extent that the need for crop adjustment seemed obviated. It raised false hopes among the farmers, belied the statistical evidence that farm production was overexpanded, and deceptively narrowed the

spread between the current and the fair exchange values of wheat and cotton.

Speculative commodity prices, with minor exceptions, advanced steadily during the spring and summer. Tremendous trading activity followed the banking holiday in March. After the embargo on gold exports, the volume of trading in speculative commodities rose until it was five times greater than the average volume during the previous winter. It culminated in July with a frenzied activity in which the trading became ten times greater than that of the winter period. Prices of 10 speculative commodities showed an average advance of more than 100 percent between March 1 and July 15. Grains, hides, and rubber rose much more than that.

Speculation in grain developed with returning confidence in the business outlook and with talk of monetary inflation. As prices advanced, buyers imagined the gains would continue indefinitely. Forgetting previous reactions from unbridled speculation, the public rushed again into the speculative markets in a blind struggle to profit from an expected boom.

Undoubtedly the prime motive was a desire to anticipate depreciation of the dollar. Speculators apparently ignored other considerations. They forgot the enormous wheat carry-over and exaggerated the significance of the small current crop. Wheat, which had advanced 30 cents a bushel between March 1 and June 19, jumped another 40 cents within the next 30 days. At one time wheat futures at Chicago were 32 cents above the Liverpool futures. Open commitments in the Chicago wheat futures increased from 151 million bushels on June 1 to 200 million bushels on July 19. The latter figure was double the 10-year average for that period. Normally the open commitments moderately exceed the visible supply of grain. Last winter the visible supply exceeded the open commitments. In the speculative boom of May, June, and July last, the open interest shot up until the total for wheat, corn, and oats exceeded the visible supply by nearly twice the normal excess. This showed exceptional outside participation in the market.

This speculative activity, and the price advances temporarily produced, ended in an utter collapse. Wheat prices dropped from a high point of \$1.24 a bushel for the December futures on July 18 to a low of 93¾ cents on July 20, a drop of 30 cents a bushel or nearly 25 percent in 2 days. American grain history had no previous record of so sharp a drop. Speculative buying had much to do with the advance in cotton prices that took place between March 1 and the third week in July. In that period prices in 10 spot markets advanced from 5.90 cents a pound to 11.51 cents a pound. The ensuing reaction, however, was not so sharp in cotton as it was in wheat. Cotton averaged 9.27 cents a pound at 10 markets on August 29. At this point cotton prices in terms of gold were barely higher than in March.

In October 1932 the previous administration suspended in part the reporting requirements of the Grain Futures Act. Exchange members thereupon ceased furnishing to the Government certain daily reports whereby the Government had been kept informed regarding the market operations of large traders. Instead the Chicago Board of Trade agreed to see that trading system would be properly conducted and to inaugurate a reporting system of its own. In ap-

proving this change, the previous administration announced that the modification "would remain in effect until notice of hearing on the reinstatement of the regulations shall have been given or until undue price fluctuations or price levels occur which indicate manipulation of the market." It cannot be asserted positively that the market would have gone less wild had the reporting regulations remained in effect. In all probability, however, these regulations would have exercised some restraining influence.

After the slump on July 19 the Government restored the reporting requirements. The Chicago Board of Trade acted to prevent a panic. It suspended one large speculator, closed the futures market for 2 days, and fixed temporary price limits. It prohibited trading in futures at prices falling below or rising above the closing prices of the previous day by more than certain amounts. It abolished trading in indemnities, otherwise known as "bids and offers." Officials of the exchange declared that trading in indemnities had been largely responsible for the accumulation of unwieldy speculative lines. The exchange, they said, had no knowledge of the commitments thus made.

The grain exchanges on September 9 formally submitted a code of fair competition to the Agricultural Adjustment Administration, with an application for a formal public hearing.

The code as submitted proposed a sliding minimum-percentage scale for margins on futures contracts, continued the existing limitations on daily fluctuations, and provided that removal of the limits be subject to approval by the Secretary of Agriculture. It contemplated the self-policing of trading by a special force of non-members in each exchange, and contained clauses regulating employment conditions. It had the formal approval of the Chicago Board of Trade, the Minneapolis Chamber of Commerce, the Duluth Board of Trade, the Omaha Grain Exchange, the Merchant's Exchange of St. Louis, the New York Produce Exchange, and the Milwaukee Grain and Stock Exchange. The Kansas City Board of Trade and the Buffalo Corn Exchange announced their intention to sign the code.

The sliding minimum-percentage-margin requirements provided for a 10-percent margin for individual purchases or sales of any one grain up to 250,000 bushels, a 15-percent margin on sales or purchases of between 250,000 and 2,000,000 bushels, and a 20-percent margin for more than 2,000,000 bushels. Hedging and spreading trades, and trades offset by future trades in another grain or in provisions on the same or another exchange, were to be exempt from minimum-margin requirements.

The Functions of Trading in Futures

Trading in futures is an important part of our present system of grain marketing. A reasonable amount of speculation gives a liquid character to the futures markets and aids in furnishing a readily available means whereby grain merchants may hedge their risks. Trading in futures also serves as a barometer of prices, a reflection of market factors, material and psychological. But it is one thing to recognize a legitimate place for futures trading and another to accept uncritically all the abuses to which it may give rise.

Uncontrolled speculation, particularly uncontrolled speculation by individual large operators, destroys whatever value the system may normally possess. Such speculation, always obnoxious, becomes particularly obnoxious when the country is engaged in efforts to regulate farm production. Uncontrolled speculation does not go well with controlled production.

Government supervision has had a wholesome effect and has curbed grain speculation materially and usefully since the Grain Futures Act was passed in 1922. It has caused the elimination of many faulty practices and has led to remedial action by the grain exchanges themselves. It has met with opposition, chiefly from persons who maintain that speculation stabilizes markets and lessens price fluctuations. The most violent opposition has always come from those who profit most in commissions or desire other monetary gains from a large volume of speculative business.

Up to a certain point, speculation may have the effect of stabilizing markets and lessening price fluctuations. Beyond it, opposite results develop. Information furnished to the Government under the terms of the Grain Futures Act has shown repeatedly that uncontrolled speculation dominates price movements for short periods to the injury of the farmers and the community in general. Individuals have sometimes held speculative lines exceeding 10,000,000 bushels. Single traders have, on certain days, done a volume of business exceeding 10 percent of the total futures business done on those days. Federal supervision of grain-exchange trading is necessary, as this year's experience demonstrated anew.

It is perfectly true that improper speculation, if it takes place on the exchanges, does not wholly originate there. There is consequently no point in blaming the exchanges exclusively. Speculation has wide-spread sources among the general public, among people who want to put themselves in a favorable relation to changing values. They may realize fully that the collective result of their individual speculations may be disastrous; but they are as powerless to control the result as are farmers acting individually to control farm production. It is imperative for the Government to supervise, and if necessary to regulate, grain speculation, because such supervision is the only means of preventing abuses.

FARM INCOME FROM 1933 PRODUCTION

It is not yet possible to estimate closely the probable gross farm income from the sale and home consumption of farm commodities produced in 1933. Available data indicate \$6,100,000,000 as the total. This estimate will be revised next spring, on the basis of more complete figures as to marketings and prices. Returns to the farmers will be augmented by payments from the Agricultural Adjustment Administration for the curtailment of acreage and other restrictions in agricultural production. The total of these payments is not yet definitely known. It is conservatively estimated at \$300,000,000, which amount will bring the total gross income of the farmers to about \$6,400,000,000. This is a substantial increase over the \$5,143,000,000 received in 1932; but it is below \$6,911,000,000, the income in 1931.

In the prospective increase the major factor is a sharp advance in the prices of nearly all farm products. Part of the advance was a response to a decrease in crop production, and to the resulting diminution in the volume of the surpluses. Part reflected an increase in consumer purchasing power, and an increase in the utilization of farm products by industry. Marketings of livestock, however, increased somewhat, owing to feed shortages and poor conditions in ranges and pastures. The increase in the supply of meats was accompanied by only a moderate improvement in consumer demand, and it restricted the income from livestock.

The index of farm-commodity prices advanced from 49 percent of the pre-war level on February 15 to 76 percent on July 15. It declined somewhat thereafter but on August 15 was still 40 percent above the February level and nearly 20 percent above the level of August 1932. Farm-commodity prices in the last quarter of the year are important in determining the gross farm income, and changes in this period may affect materially the estimate given above. There was a close relationship during the spring and summer between the farm commodity price level and the trend of business activity. A continued increase in industrial activity would undoubtedly mean additional improvement in the demand.

Reduced Supplies Strengthen Prices

Reduced production strengthened the supply situation. Wheat output was below normal domestic requirements, and the carry-over declined for the first time since 1926. However, the supply remained excessive. Supplies of other grains were less burdensome, though the carry-overs were large. Production in 1933, however, was greatly reduced, and the total supply of feed grains is now below the supply in any of the last few years except 1930. By taking out of production approximately a quarter of the acreage planted to cotton, the growers of that commodity reduced the season's output to a point below the world's average annual consumption of American cotton. As previously noted, however, the production and the carry-over combined constituted an excessive supply.

Production of cigar-type tobaccos, which had exceeded the consumption for several years, was reduced by more than 30 percent. This curtailment resulted partly from the reaction of the growers to the unusually low prices that prevailed last year and partly from the acreage-reduction campaign of the Agricultural Adjustment Administration. Low prices caused a reduction in the output of many other crops, such as potatoes, flax, rye, and numerous truck crops, with favorable effects on their market position. On the other hand, the production of most of the major fruit crops slightly exceeded that of 1932, though remaining below the average. The demand increased, however, as a result of improvement in the economic situation generally, and the prices of most fruits ruled higher than in the previous season.

Inspected slaughter of hogs in the first half of 1933 was 3 percent greater than in 1932, and the average cost to packers declined. This cost was \$3.72 per hundredweight, as compared with \$3.74 during the first half of 1932. Slaughter in the second half of the year will probably exceed that of the second half of 1932, because the number

of hogs 6 months old and over on June 1 showed a 13-percent increase, and there was an increase of 3 percent in the number of spring pigs saved. In the Corn Belt the increases amounted to 20 and 4 percent, respectively. The Administration's plan for buying sows bred to farrow in the fall and pigs under 100 pounds will not affect materially the amount of pork available for market during the remainder of the present year. It will improve the market, however, and will greatly reduce the prospective supply for the first half of 1934.

Cattle and calf slaughter likewise was larger this year than last. In the first half of 1933 the inspected slaughter of cattle exceeded that of the corresponding period in 1932 by nearly 6 percent. Yet the cost to packers was about 12 percent less. An increased number of cattle and unfavorable range and pasture conditions over much of the country caused increased fall marketings, and with outlets reduced, slaughter increased sharply. Calf slaughter during the year showed an increase, and calf prices ran below those of 1932. Sheep and lamb slaughter fell slightly below that of 1932. Prices of new crop lambs during the summer went above the level of the previous summer. The gross income to farmers from all livestock sales during the first half of 1933 was lower than during the same period in 1932. Income for the second half will be larger.

From March to August factory employment and pay rolls increased 22 and 39 percent, respectively, and such changes usually produce somewhat later an improved consumer demand for meats.

Income From Livestock and Poultry

Farm income from livestock products and from poultry and eggs in 1933 seems likely to be about the same as it was in 1932. Among these products, wool shows the greatest change. The season's clip was only about 1 percent greater than that of 1932, and there was a marked increase in wool textile activity. In consequence, the summer witnessed one of the sharpest advances in wool prices on record. In the most important marketing period for wool, April to July, inclusive, the farm price of wool averaged 18 cents, as compared with 8.5 cents in the corresponding period last year.

The production of milk on farms during the first half of 1933 was about the same as that of the first half of 1932, though the number of cows on farms was larger. High-priced feed and poor pasture conditions tended to restrict milk production. In the first half of the year the prices of whole milk and butter averaged below those of the first half of 1932, but July and August prices were above those of the same months last year. If the improvement continues to the end of the year, the gross income from dairy products should equal that of 1932.

There is an increased supply of poultry for market, but owing to heavy marketing of layers due to low prices of eggs and increased prices of feeds the supply of fresh eggs for the fall and winter will probably be less than that of last year. Up to the middle of September the prices of eggs ruled about the same as in the corresponding period of 1932. The prices of chickens ruled considerably lower. The total income in 1933 from poultry and eggs will probably be little less than that of the previous year.

The Price Trend

In February the general level of the prices of farm products, and also the exchange value or purchasing power of these goods in terms of other commodities, reached the lowest point on record, 49 percent of the pre-war average. The farmer had to bring two wagon loads of farm products to market in order to get in exchange the same quantity of other things that he could have obtained for one wagon load in the period 1910-14.

Some farmers increased their production and sales in an effort to maintain their standard of living. Nevertheless, the broad result was a sharp curtailment in purchases by farmers, who lived more nearly on what could be produced on the farm. All branches of business felt the effect. Reduced buying by farmers cut down industry, employment, and pay rolls. In this paralysis of trade between the country and the town, farmers saw no hope of escape from the necessity of selling their products below cost. They fed the cities, at the price of their own progressive ruin.

In March the new administration initiated the legislative program which produced the Agricultural Adjustment Act and the National Recovery Act. It dealt with the banking crisis and with monetary problems. Farm-commodity prices improved slightly in March, and substantially in April and May. In July there was sharp speculative advance followed by a reaction. From mid-March to mid-October, however, the net gain was 47 percent. There was not so great a gain—only 22 percent—in the exchange value of farm products from March to October, because prices paid by farmers advanced considerably. Some farmers, notably the beef-cattle men, lost purchasing power between March and October.

Among numerous factors that contributed to the advance in farm commodities were a reduction in the supply of some products, a general belief that economic conditions were improving, depreciation of the dollar in foreign exchange, increased business activity and employment, the replenishing of depleted stocks of goods, and increased buying by consumers in anticipation of higher prices. Reduction in supplies had much to do with the advance in the prices of grain and potatoes. The wheat and oat crops were the smallest in 40 years, and the corn crop was the next to the smallest since 1901. As already noted, however, the carry-over of these grains was above the average. A 14-percent reduction in the potato crop was more than offset to the growers by price gains. Market supplies of cattle, hogs, and butter were unusually large; nevertheless the prices of these products were fairly well maintained.

Depreciation of the Dollar

The depreciation of the dollar in foreign exchange affected mainly cotton, tobacco, and grain. It had less influence on most other farm products, and very little on those governed chiefly by local condition. On October 31 the dollar was worth only 64.4 cents in terms of French, Dutch, and Swiss gold moneys. During the summer speculation connected with the depreciation furnished additional, though temporary, stimulus to cotton and wheat prices. In a swift reaction these commodities fell sharply, but improved in September and October. Commodities sold mainly in the domestic market did not

advance materially, except in cases (as for example potatoes) in which supplies were greatly reduced. Beef-cattle prices in October were about as low as they were in March, and in terms of gold as well as in purchasing power were decidedly lower than in March.

It is important to compare the above-mentioned domestic price movements with price movements in other currencies. From early April to the third week in July, wheat prices at Chicago in terms of the dollar advanced 84 percent and cotton prices at New York advanced 71 percent. In terms of sterling during the same period, wheat and cotton prices at Liverpool advanced only 22 percent. Comparing prices for the fourth week in October with the level of prices during the first half of April, wheat prices at Chicago in dollars had advanced 48 percent whereas wheat prices at Liverpool in sterling were 3 percent lower; in terms of gold wheat prices at Liverpool were 11 percent lower in the fourth week of October than in the period April 1 to April 15. Cotton prices for the fourth week of October compared with the level of prices for the first half of April were 44 percent higher at New York in terms of dollars and 45 percent higher at Liverpool in terms of dollars, but only 6 percent higher in sterling at Liverpool and 3 percent lower at Liverpool in terms of gold.

Broader effects on prices seemed likely to result from the gold-purchase policy adopted by the Government in October. This policy, by gradually increasing the price of gold, indicates an intention eventually to cut the quantity of gold in the dollar. It may not have any great effect for some time on livestock and dairy prices, which depend much more on pay rolls in this country than on foreign demand. Eventually, however, most of our raw-material prices should rise to the extent to which the gold in the dollar is reduced. It may take certain products a year, or even several years, fully to reflect the change. It is well to bear in mind the probability that the favorable influence of our monetary policy on the prices of cotton and wheat may not continue if foreign countries reduce the weight of gold behind their currencies as rapidly as we do. Currency policies may stimulate our exports temporarily but should not lead us to think that a world-wide demand exists for our surpluses, unless sufficient changes have been made in our tariffs to build up sufficiently increased foreign purchasing power.

Varied Response to Recovery Factors

As usually happens when the general price level is changing, different farm products varied greatly in their response to recovery factors. The average of prices received by farmers in October was 43 percent above the low point of the depression. At one extreme, wool showed a gain of 237 percent; at the other, beef cattle rose only 7 percent. Corn in mid-October was 106 percent above the low point touched on December 15, 1932, whereas hogs showed a gain of only 56 percent. Tobacco prices advanced over the relatively high prices of the previous year which were the result of a short crop. The exchange value of farm products in mid-October was 60 percent of the pre-war average, compared with 71 percent at the season's high point in mid-July. This decline from July to October reflected both a decrease in prices received by farmers and a continued increase in prices paid by farmers for commodities bought.

It should be noted, in connection with the advance in the prices of the things that farmers buy, that this advance included part of

FIGURE 2.—Indexes of prices received and paid by farmers. The recovery efforts since March have brought about a sharp advance in certain farm products, particularly grains and cotton. The prices of these commodities had previously fallen to lower levels than the prices of most other farm products. They responded promptly in 1933 to the administration's monetary policy. Commodities more nearly on a domestic basis, such as meat animals, dairy products, and poultry products, did not rise equally as a result of monetary changes, but showed some advance. A small crop of potatoes caused a great advance in potato prices and raised the average for the fruits and vegetables group. The advance in prices received by farmers was partly offset by a 17-percent advance in prices paid by them. But returns to cotton growers and wheat growers were augmented by benefit payments for acreage reductions. These payments meant practically parity returns to the growers. Benefits to farmers during the 5 months from August to December were equivalent to a 20-percent increase over their cash farm income for the same period last year.

the gain in the prices of farm commodities. Rising grain prices during the summer obliged farmers to pay more for feed and for

such foods as they purchase. Building materials, equipment and supplies, fertilizer, machinery, and other things used in farm production increased in price also; these things, however, include comparatively little raw material from the farm. In mid-October the index of the prices paid by farmers for commodities used in family maintenance stood at 119, as compared with 99 in March. The separate index for the prices of commodities used in farm production was also 113 in October, as compared with 101 in March.

FARM REAL ESTATE VALUES

The total value of farm real estate in the United States fell from \$37,027,000,000 as of March 1932, to \$30,515,000,000 as of March 1933. These values compare with \$47,880,000,000 in 1930 and \$66,316,000,000 in 1920.

The acre value of farm real estate declined in nearly every region. The average for the United States, as of March 1933, was 27 percent below pre-war (1912-14), as compared with 11 percent below for the previous year. The peak of values, 70 percent above pre-war, was reached in 1920.

Present low levels are the result of two fairly distinct movements. The first lasted from 1920 to 1930. In that period, during which the effects of the speculative wave in the war and post-war boom were largely liquidated, the Department's index of land values dropped from 170 to 115, a decline of 32 percent.

During the second broad movement, which became clearly evident in 1930, the index declined from 115 to 73 in 1933, a decline of nearly 37 percent. This drop reflected the drastic decline in the price level during the depression.

The relative decline in farm real-estate values has been greater during the past 3 years than during the whole decade following 1920.

In only 7 States, 4 of them in New England, was the index of land values higher in March 1933 than in 1912-14; in some States it was less than 60 percent of the pre-war index.

In the Middle Atlantic States values averaged 82 percent of pre-war, in the East North Central States 62 percent, and in the West North Central States 64 percent. The index for the South Atlantic States was 80 percent of pre-war, for the East South Central States 79 percent, and for the West South Central 82 percent. Values in the Mountain States averaged 69 percent of pre-war and in the Pacific States 96 percent. The New England States, where the index was 105, were the only group in which average values were higher than in 1912-14.

Forced sales of farms increased as a result of delinquency on taxes and on debt service. For the year ended March 15, 1933, approximately 15.3 farms per 1,000 were sold for taxes. Approximately 38.8 per 1,000 were involved in transfers in settlement of debt. Corresponding rates for the previous year were 13.3 and 28.4 farms per 1,000, respectively.

These transfers of title are not necessarily final in every case, since periods of redemption are frequently provided by State statutes.

FARM DEBTS

One of the worst aspects of the farm problem is the farm-debt situation.

In 1928 farm-mortgage indebtedness in the United States amounted to nearly \$9,500,000,000, and short-term indebtedness, represented chiefly by loans from local banks, ran to about \$3,000,000,000 more. Farmers owed large additional sums to livestock-loan companies, farm-implement companies, and merchants. Total farm indebtedness undoubtedly exceeded \$14,000,000,000. On the real estate indebtedness, the annual interest charge averaged about 6 percent. On the short-term bank indebtedness the interest charge averaged probably 7.5 percent. On merchant credit the interest amounted to 10 or more percent. This Department estimated the annual carrying charge for 1928 at \$900,000,000.

By 1932 the mortgage indebtedness had been reduced to about \$8,500,000,000, and the total of other forms of farm indebtedness had declined also. Ordinarily, a reduction of indebtedness is a favorable sign, an indication that debtors are improving their financial position. Sometimes, however, it is an unfavorable sign. This is, in large part, the case with the decline of farm indebtedness in this country since 1928. It is largely a result, not of normal liquidation, but of foreclosures, bankruptcies, and forced sales, and of the inability of local banks and other credit agencies to lend. Forced sales in 1932 constituted 37 percent of all transfers, as compared with 27 percent in 1928. Moreover, the reduced carrying charge represents this year a much greater proportion of the gross farm income than did the larger payments in 1928. Mortgage carrying charges alone will take this year something like 13 percent of the gross farm income.

In 1932 for the country as a whole nearly 16 percent of all mortgaged farms were encumbered for more than 75 percent of their value. The mortgage debt represented 25 percent of the value of all farm land and buildings, and about 40 percent of the value of all mortgaged farms. It was two and a half times greater than in 1910. Even in 1929, before the depression, farmers had difficulty in meeting their interest charges and in retiring maturing loans. Even then they were not getting a fair exchange value for their products. When farm prices dropped in the depression to 50 percent below pre-war, payment became impossible for great numbers of farmers, especially those carrying heavy indebtedness.

Difficulty in Getting Renewals

Their plight, because of delinquency and lower land values, was intensified by an increasing difficulty in renewing mortgages at their original amounts. About 12 percent of the farm-mortgage indebtedness normally comes due each year. Delinquent interest and principal payments have automatically increased the number of loans for which payment has been called. Reduction of the total debt through foreclosures means that farmers are being forced to the wall. The need, in existing circumstances more than ever before, is for refinancing of mortgage debts pending a further improvement of farm income. Mortgage interest is in arrears on thousands of farms that have not yet been brought under the hammer.

The depression disrupted short-term credit facilities as badly as it did mortgage facilities. Country bank failures multiplied. After the general bank suspension in 1933, more than 3,000 banks, mostly in rural areas, failed to reopen or reopened only for restricted withdrawals. Deposits dropped in the banks that did not fail. In 20 leading agricultural States, the 4-year period ended in February last saw a decline of more than 50 percent in the net demand deposits of member banks in the Federal Reserve System in cities and towns of less than 15,000 population.

This summer there was a partial recovery, but the level of deposits still remained 14 percent lower than in the midsummer of 1932. Low bank deposits mean low bank lending power. This may reduce farm production, but the method is bad. Many farmers cannot adequately carry on their farming operations when production credit fails.

Farm credit difficulties, though especially acute since 1929, did not begin then. Credit facilities have been inadequate in many rural areas for years. The Federal Government has attempted frequently since the war to improve the situation through emergency measures and new permanent agencies. In 1921 it enabled the War Finance Corporation to advance funds to livestock-loan companies and to banks in agricultural communities. In 1923 it established the Federal Intermediate Credit Banks. In 1929 it financed cooperative marketing organizations through the Federal Farm Board. In nine different years it provided money for seed loans. It authorized the Secretary of Agriculture to assist in capitalizing agricultural-credit corporations and livestock-loan companies and authorized the Reconstruction Finance Corporation through the regional agricultural-credit corporations to make direct loans to farmers on the security of livestock and other personal property including growing crops.

These various activities did not suffice, however, to meet the critical situation that developed as the depression continued. Accordingly Congress took additional action, along the lines previously described in connection with the passage of the Agricultural Adjustment Act.

It is not within the scope of this report to discuss the administrative side of the new Federal credit policy, because that is the responsibility of the Federal Farm Credit Administration. That body coordinates the credit functions of the former Federal Farm Board and also of the Federal Farm Loan Board, which has charge of the Federal land banks and the intermediate credit banks. Also it supervises the administration of the regional credit corporations and the various emergency-loan funds previously administered by the Department of Agriculture. Formerly these various Federal credit functions in many cases overlapped, and farmers often did not know where to apply for the particular kind of credit they needed.

By strengthening the capital structure of the Federal land banks and furnishing substantial sums for mortgage loans to farmers, Congress gave private lending agencies an opportunity to transfer loans which they could not hold, and thus to avoid foreclosing on the farm borrowers. It relieved farmers materially by authorizing the Federal Farm Credit Administration to reduce the interest rate on Federal land bank bonds, and temporarily to waive payments on the principal. In addition it made direct loans available to farmers in districts where local farm-loan associations are not in a position to accept loan applications.

It will take time to realize the potentialities of the new legislation in tangible benefits to the agricultural industry, but the ultimate showing should be very substantial. Already the foreclosure process has dropped off considerably.

New Credit Agencies

Under the 1933 credit legislation, the Farm Credit Administration may set up in each Federal bank city two new credit agencies, a production credit corporation and a bank for cooperatives. The production credit corporation may purchase stock in local credit associations which function as discounting agencies with the Federal intermediate credit banks. Borrowers through these associations will be required to buy stock in them. The cooperative bank may make loans to farmers' cooperative associations organized not only for the sale of farm products but also for the purchase of farm supplies.

Besides the 12 national cooperative banks, the Farm Credit Administration has set up in Washington, D.C., a central bank for cooperatives. This institution will make loans to the major cooperative associations about in the same manner as did the Federal Farm Board.

Banking Difficulties

More than a decade of serious banking difficulties in agricultural communities has made banking reform a problem of great importance to farmers. More than 10,000 banks have failed in the United States since 1920. In mid-August this year, about 2,800 banks were restricting withdrawals. Most of these banks were in agricultural communities. Such figures indicate the difficulties that farmers have had with their banks. The loss to both depositors and borrowers arising from bank receiverships has been tremendous, and the lending power of open banks has been drastically curtailed.

The trouble in country banks arose mainly from withdrawals by depositors and from a frozen condition of the loans and investments. These conditions, present as troublesome factors for many years, were greatly intensified by the depression. Growing disparities between income and necessary expenditures in agricultural areas caused deposit declines, which thousands of country banks, because of their frozen condition, could not meet. The depression rendered loans less collectible and depreciated the value of bonds to the point where, in many cases, banks dared not sell their bonds. Caught between these two millstones, thousands of country banks were forced to close or to restrict withdrawals. This created a condition of public distrust which further aggravated the situation.

Difficulties arising from the depression, however, would have caused far less widespread damage had not the banking situation already been weak. Studies participated in by the Bureau of Agricultural Economics show that before the depression set in numerous country banks had large holdings of poor loans and speculative bonds, and that most country banks were deeply involved in financing the long-term needs of farmers and businesses in their communities. They were able to do this because their time and savings deposits, added to their current deposits, gave them a lending power far in excess of the amount that farmers and local industries needed for current operating purposes.

Financing of this character does not usually reveal its weakness until depositors begin reducing their accounts. Then it becomes apparent that loans for long-term purposes cannot be collected except on a very small scale. If, combined with local withdrawals, there is a general depression of values which reduces the collectibility of loans and which impairs the values of bonds, banks often find it impossible to meet the demands of depositors.

Loans for the current operating purposes of farmers and business men can be discounted at Federal Reserve banks, even if they are not immediately collectible; hence these loans are seldom responsible for the failure of banks. But there is virtually no outlet for most of the paper representing advances for the long-term purposes of farmers and local business men. Although many banks have successfully weathered the depression in spite of their large holdings of slow loans and depreciated bonds, few have been able to do so when local unrest has caused deposit withdrawals of very large extent.

Means of Strengthening Country Banks

A means of strengthening country banks is suggested by the fact that banks become deeply involved in long-term financing mainly because their lending power greatly exceeds the volume of credit that farmers and local business can absorb in liquid operating loans. This, in most banks, results from the large volume of their time and savings deposits. Were these accounts removed from commercial banks, such banks would be able to keep in much more liquid condition. Segregated in savings banks or loan companies the time and savings deposits would be a source of little difficulty, for these institutions could easily call a halt upon runs by depositors. The bank which handles both kinds of accounts cannot do this, because an attempt to restrict one type of deposit actually creates runs by other types of depositors.

Segregating the time and savings deposits in the manner indicated might seem to work an injustice upon the depositors, particularly if restrictions were placed upon withdrawals. It is obvious, however, that no considerable amount of time and savings deposits can be paid in a short period of time by any type of banking system. The funds representing these deposits are invested in the fixed capital of agriculture and industry, and cannot be extracted at short notice. Taking such accounts out of commercial banks would merely make it impossible for time and savings depositors to force a general banking collapse by attempting to withdraw their money.

FARM TAXES

Farm taxes per acre in 1932 were 89 percent higher than in 1913. This Department has completed a study to determine changes in farm real-estate taxes per acre and in relation to value for each of the 48 States. By 1929 the taxes per acre had risen on an average 141 percent above the pre-war year 1913. In every geographic division they had more than doubled.

Since 1929 acute distress among farm taxpayers has forced reductions in tax rates, in assessments, or in both, in all but three States. The average tax reductions, though substantial, have been very unevenly distributed among taxpayers. Many have had no reduction

from the 1929 level. Indeed, in three States the averages have not decreased.

In 1913 taxes amounted to an average of 55 cents on each \$100 of farm valuation. By 1929 the figure had increased to \$1.19. In the second post-war depression land values fell more rapidly than did taxes, with the result that in 1932 farm taxes amounted to \$1.50 per \$100 of farm valuation, or nearly three times as much as in 1913.

Farms in ever-increasing numbers became tax delinquent. A great part of the delinquency followed the severe drop in farm prices and income in 1929 and later. A significant increase was evident, however, before 1929.

The tax burden on farmers results primarily from the undue reliance of State and local governments on the general property tax, from the discriminatory weight of this tax upon real estate, and from the relatively great amount of real estate required in a farming business. The so-called "general-property tax" is little more than a real-estate tax and falls with special severity on farm owners. Less reliance should be placed on the general-property tax as a source of State and local revenue, and the efficiency of rural government should be improved through a revision and redistribution of functions, and through a reorganization or consolidation of governmental units and of administrative machinery.

EXTENSION AND INFORMATION WORK

The extension services of the Department and the various States have been the spearhead of the educational effort to acquaint farmers with the purposes and opportunities of the various programs undertaken under the Agricultural Adjustment Act.

With experienced local farm agents in 2,200 counties, and other agencies at work in 700 other counties, the cooperative extension service was well organized to assume the advisory and informational responsibility. Special temporary agents were assigned to many counties with high agricultural production, to aid in the emergency work. Federal and State specialists and administrative staffs threw their efforts, backed by years of experience, into supporting the field agents in interpreting and instructing in the national programs of agricultural adjustment.

First of all, farmers were given the fullest possible information on current economic situations in agriculture. The disastrous results of great surpluses of wheat, cotton, hogs, and other basic agricultural products were outlined. Farmers gained a new understanding of the "shadow of excess." They caught the significance of closed export markets. They realized the vital need of adjusting production with effective demand.

Then came the first of the basic production reduction programs—the emergency plan which took more than 4 million bales of cotton from the potential 1933 crop. Supported by more than 20,000 volunteer workers, the extension staff in the South led the campaign in which more than a million cotton growers signed contracts to reduce their 1933 crop acreage. Fighting against time from the start, the entire campaign was pushed through in 6 weeks.

Working simultaneously in more than 30 States, the cooperative extension forces carried out the educational and organization features of the national wheat adjustment campaign, launched by the Agri-

cultural Adjustment Administration as a 2-year production-control program. Wheat growers signed voluntary applications bringing more than 50 million acres of wheat under the agreements, which call for a 15-percent reduction in 1934 acreage. Extension representatives helped hundreds of local wheat production-control associations, composed of the participating farmers themselves, to organize. These associations will carry out much of the local administration of the wheat plan.

In production-control campaigns for various types of tobacco in different districts, and in carrying out the emergency hog-marketing plan, the extension staffs performed field activities. In the more permanent cotton, dairy, and corn-hog adjustment programs, as well as in many more localized activities in the general campaign to restore the pre-war purchasing power of farm products, the widespread cooperative extension service has been in position to carry out the needed educational and organization work.

Home-demonstration agents, located in more than two thirds of the counties of the United States, have cooperated with the consumers' counsel of the Agricultural Adjustment Administration in helping the home makers of the country to meet changing economic conditions. They have done a great deal of work with local relief agencies, assisting with meal planning and dietary recommendations, encouraging home gardening, conducting food-canning demonstrations, and helping plan emergency budgets. The home-demonstration agents have also directed activities which have helped to keep families off the relief rolls. They have supported the live-at-home program, which has made it possible for many families to be largely self-supporting.

Even in the midst of efforts to solve great economic and social problems, the interest of the entire country, both rural and urban, in the 4-H clubs has been sustained. 4-H club membership and work have kept up their excellent records. Young people have, perhaps, been most keenly interested in ways to assist in the family's problems and in projects which promised some profit.

As details of commodity adjustment efforts were more sharply defined and the various phases were woven into a strong national agricultural plan, extension agents adapted their programs to carry on both the vital adjustment work and their regular responsibilities in helping to solve the ever-present problems that face the American farm family—reduction of expensive loss and waste in farm operations, better utilization of labor and facilities, economical improvements in quality of products, provision of satisfactory standards of living, and maintenance of the morale of the family.

Publications, Press, and Radio

Supplementing the extension efforts on the adjustment program, the information staff of the Department carried out the largest single, intensive effort it has ever made to unify the thinking and action of farmers. By issuing publications, by cooperating with the press of the country, and by broadcasting daily over 300 radio stations, the Department acquainted farmers with facts about current supply-and-demand maladjustments, prices, and possible remedies, and about the basic principles and powers of the Agricultural Adjust-

ment Act. The purpose was to give farmers facts on which they could intelligently shape a program designed to improve their economic conditions and, acting in unison, use the centralizing power of the Federal Government to make that program work.

Machinery for handling information was reorganized. Previously the press work of the Department and of the State extension services was carried on more or less independently. During the early part of May arrangements were made to clear some of the Department's press material through the agricultural extension editors in the 48 States. Seventeen State extension services were already cooperating with the Department in correlating agricultural radio programs; this number was quickly increased to 41, thus providing an effective Federal-State channel for the daily distribution of information. Finally, a special information unit was established in the Agricultural Adjustment Administration to give the public each day accurate accounts covering actions taken and policies decided upon.

In previous years the principal function of the information staff was to interpret and place in the hands of those who could apply them, the facts and recommendations arising from the scientific, economic, regulatory, and conservation work of the Department. The new program does not supplant the other work; in fact, technical knowledge has become of increased importance to farmers and others. But greatest emphasis is now placed on economic and social adjustments which have a single purpose—increasing the buying power of farm commodities.

PLANT INVESTIGATIONS

Sugar Beets

Plant investigations developed strains of sugar beets resistant to leaf spot. Hybrids produced by intercrossing surpassed the commercial strains in tonnage and sucrose percentage. The introduction of these leaf-spot-resistant hybrids is now definitely forecast. For large areas in the Middle West they will provide a measure of relief against a disease which has in many seasons made crop production and factory operation unprofitable.

Curly-top-resistant variety U.S. No. 1, a recent development, proved superior to ordinary sorts in seasons when the curly-top disease was important and compared favorably with the best commercial varieties in seasons when curly top was unimportant. It produces a slightly lower tonnage but equals the commercial strains in quality. It will be distributed to growers for testing in 1934.

New Egyptian-Type Cotton

Comparative field tests under diverse conditions of climate and soil indicated that a new hybrid obtained by crossing Pima, the only variety of Egyptian-type cotton grown commercially in the United States, and Sakel, the most valuable of the varieties grown in Egypt, may be depended on to outyield Pima 20 percent. Spinning tests are being conducted to determine the value of this new hybrid in comparison with Sakel.

Downy Mildew of Tobacco

Laboratory studies indicated that although spore germination and plant infection can occur over a wide range of temperatures, spore production takes place only with night temperatures between 50° and 60° F. Maintaining night temperatures at 70° gives effective control. In most localities the critical period over which such temperature control is needed probably does not exceed 3 weeks.

Barley—Oats—Wheat—Flax—Corn

Analysis of 5 years' yield from the entire United States and Canada shows that Trebi barley, introduced by the Department, has a remarkable range of adaptation. It was the highest yielder at 31 stations, no other variety leading at more than 4 places. It is not considered satisfactory for malting purposes, but is a high-grade feeding barley.

Bond, Alber, Berger, and Victoria oats recently introduced by the Department from Australia and South America are proving highly resistant to crown rust which seriously limits the production of winter oats in the South. The first three, moreover, show indications of being adapted to different sections of the South. Some very promising hybrids involving these varieties are being developed.

A new wheat variety, Yogo, developed in cooperation with the Montana Agricultural Experiment Station, is unusually winter hardy, resistant to bunt, and well adapted to, and high-yielding in, the northern winter-wheat section of the Great Plains.

Browning (*Polyspora lini*), a disease new to the principal seed-flax areas of the United States, was found in North Dakota in 1932. Bison, highly resistant to flax wilt, is very susceptible to the browning disease. Other commercial varieties appear to be quite resistant to it. Periods of low temperature during the early and late growing season seem to favor the spread of the disease.

Seed of parent lines of four corn hybrids, developed in cooperation with the Iowa Agricultural Experiment Station, has been placed with farmers for production on a commercial scale. In 1932 these four hybrids produced yields 14 percent greater than did the average of open-pollinated varieties grown in the Iowa corn yield test. They are markedly more resistant to lodging than the open-pollinated corn, and otherwise more valuable.

Crotalaria—Lespedeza

The use of crotalarias for soil improvement, especially in orchards of tung-oil trees and in citrus groves on sandy soils, has greatly increased because these plants are not infected by the root-knot nematode. This is of the greatest importance for any soil-improving crop for sandy land in the South as far north as the peach area of North Carolina. At least one species of crotalaria has been found useful for soil improvement as far north as the Ohio River, wherever the type of farming allows the use of a summer soil-improving crop. Other species have proved to be good forage crops.

Korean lespedeza, introduced by the Department in 1921, has now spread from the Atlantic coast to eastern Kansas, and in Missouri has reached such importance that new rotations are being built around it.

In cooperation with the Virginia Agricultural Experiment Station, the Department developed a number of stocks of Virginia-type peanuts grading 85 percent or more of extra-large size. The stocks are also higher yielders than ordinary sorts. Since a substantial premium is usually paid for large-sized peanuts, these new stocks open the way to materially increased profits for growers.

The Department bred a new early variety of the Refugee-type bean which is decidedly resistant to the mosaic disease and which is attracting the attention of canners and seedsmen. It is about 2 weeks earlier than the Refugee and shows much promise for canning. Its earliness is important because the present commercial strains are so late that in many of the important bean seed-growing districts frost occurs before the seed is mature.

Some of the Persian walnut orchards of California were made to produce a profit for the first time the past year through a demonstration of the Department's discovery that artificial cross-pollination is sometimes necessary, not because of self-incompatibility but because the staminate and pistillate blossoms of the individual varieties do not reach maturity simultaneously in some cases. The cost of artificial pollination is low, about \$3 an acre.

Handling and Transportation of Perishables

Investigations in the handling and transportation of fruits and vegetables showed that the quality of peas, baby lima beans, and sweet corn, which deteriorate rapidly after harvesting, can be maintained for several days by storage in carbon dioxide gas; and that soft scald and soggy break-down of apples may be prevented by treatments with carbon dioxide for 2 or 3 days prior to cold storage at 32° F.

The use of sodium acid sulphite mixed with the sawdust when grapes are packed has been found to prevent mold in storage of California table grapes. It preserves the grapes in sound and almost fresh condition for upwards of 3 months at 32° F. This chemical may be placed in the pad or cushion at the bottom of the package. Sodium metabisulphite may also be used.

Investigators worked out a new and more effective method of protecting pears from freezing in transit, which costs from \$10 to \$12 less per car than the old method. The latent heat of fusion of water can be employed to protect the pears from freezing. Sawdust saturated with water is packed under the lower portion of the load, and the heat liberated when this water is frozen in transit protects the fruit from freezing 2 days longer than does the use of dry straw or building paper.

Kieffer pears, the investigations showed, may be ripened to acceptable quality for dessert or canning purposes at a temperature of 60° to 65° F. This discovery is likely to prove of much importance to growers and to the eastern packing industry. The importance of proper ripening temperature for the Kieffer pear does not seem to have been realized heretofore.

Frozen-Pack Investigations

Frozen-pack investigations demonstrated that for fruit very rapid freezing is not only unnecessary but is sometimes detrimental to the quality of the product. With fruits packed in small retail containers,

the best quality in most cases, as well as the greatest economy in cost, is attained by freezing fruits at a temperature of 10° to 15° F. When the fruit is packed in barrels, a temperature of about zero appears desirable on account of the larger mass and the necessity of its being completely frozen before deterioration sets in. Expensive special equipment for very rapid freezing is not essential with this method of preservation. The facilities available in practically every cold-storage plant can be satisfactorily utilized. The limitations of this method are to be found in problems of marketing rather than in the use of any particular method of freezing. An airtight container is essential for the satisfactory preservation of certain frozen-pack fruits.

Dutch Elm Disease

A serious outbreak of the Dutch elm disease was discovered near Newark, N.J., involving more than 200 trees scattered over some 600 square miles. Other infections were found on Staten Island and Long Island. In Ohio in 1930 and 1931 this disease was found on 8 trees which were immediately destroyed, and but 1 additional tree affected with the disease has been found during the past year in that State. A control program in cooperation with the State of New Jersey is being undertaken. As rapidly as possible this work will be extended to other States in which infection is found, in the hope of saving this important park and shade tree.

Stain in Pine and Hardwood Lumber

During the past 2 years over 200 pine and hardwood mills in the United States, Canada, Mexico, and the Philippine Islands have adopted the inexpensive organic-mercury treatment developed by the Department for the control of stain and mold in pine and hardwood lumber. Recent studies have added certain new chlorinated-phenol treatments which, though costing a little more, appear still more effective on all southern commercial species of pine.

ANIMAL-INDUSTRY WORK

Much of the possible profit from hog raising in the South has been turned into loss by the kidney worm, the most widespread and destructive swine pest in this region. After many years of research on farms and at packing plants, the Department this year found a simple, practical, and cheap method of avoiding this loss which at the same time lessens the danger of spread of this pest to other parts of the country.

The method consists essentially in preventing the infection of young pigs, and in this respect is much like the original swine-sanitation system, which was also devised by the Department and which is now used widely by hog producers in the Middle West to control the roundworm. This new sanitation plan for southern farms depends on keeping the eggs and immature worms passed in the urine of the infected sows off the grass and other forage where they would be picked up by the young pigs in feeding.

Observation and a study of infestation of the soil have shown that most of the infectious material is passed in the area around the sleeping quarters and close to the fences. The eggs and immature

worms are soon killed by sunlight, heat, and drying. They cannot last long in the open unless they fall in grass or other plants. The plan, which has given good results in many farm tests, requires clearing away all vegetation, including grass and weeds, in a strip 3 to 5 feet wide along the fence on three sides of the pasture lot, and a strip about 30 feet wide at the end where the houses and other equipment are placed. These areas must be kept cleared while the pasture is in use.

Some few eggs and worms will be spread on the green part of the lot, but experience has shown that a very large percentage will be passed by the sows on the bare ground just outside the sleeping quarters, near the feeders, or along the fence. The actual results reported prove the point. In considering these results, it should be remembered that throughout a large part of the South at least 90 percent of the hogs are infested with this kidney parasite.

Near Moultrie, Ga., the Department investigators raised 125 pigs on pasture lots surrounded by these cleared sanitation strips. Only 4 percent of the pigs had worms in the kidney area, and only 15 percent of the livers were condemned at slaughter as unfit for human food, which means that 85 percent were not infected. Packing plants in this region have regularly lost about 95 percent of the livers as unfit, as well as parts of the loin, and frequently whole carcasses, all as a result of this parasite.

As a check on the lot of 125 pigs raised under the new sanitation-strip plan, 291 were raised under the original sanitation system used in the Corn Belt to control roundworms. Under this plan in the South the sows, before farrowing, are placed on a clean pasture and kept there with their pigs. The pastures in this system have no bare strips around the borders. A great reduction in infestation was the result, but it was not satisfactory. Of the 291 pigs raised this way and marketed, 23 percent had infected kidneys and 68 percent of the livers were condemned.

In addition, 28 pigs were raised in pasture lots with no sanitation measures before or during the pasture period. Thirty-two percent of them had infected kidneys, and 97.5 percent of the livers were condemned.

Bovine Tuberculosis

In the extensive Federal-State effort to eradicate bovine tuberculosis, three more States—Nevada, New Hampshire, and Utah—attained practical freedom from this disease during the last year. This brought the total number of such States to 11. Added progress in other States has increased the total number of counties accredited by the Department as free of the disease. On July 1, 1933, there were 1,626 counties, or 53 percent of all the counties in the United States, so recognized. During the fiscal year tuberculin tests were applied to 13,073,894 cattle and 255,096 were condemned. Funds made available for tuberculosis eradication by the various States and counties amounted to about \$10,000,000 for the year.

In Iowa opponents of tuberculosis eradication attempted to abolish all legislation having anything to do with carrying on this activity. Public sentiment was aroused and the attempt was defeated in the legislature. The work is now going on in a satisfactory manner in that State.

Eradication of Parasites

In the campaign to eradicate the cattle tick, the carrier of tick fever, the Department continued to cooperate with State and county officials and cattle owners in the affected Southern States. During the year Federal and State agents supervised 25,328,261 inspections or dippings of cattle, and 2,368,581 inspections or dippings of horses and mules. The following areas were released from Federal quarantine: 7 counties and part of 1 county in Arkansas, thereby freeing that whole State from quarantine; 6 counties and parts of 3 counties in Florida; and 10 counties and part of 1 county in Texas; the aggregate area released being 20,290 square miles. At the end of the year the Federal quarantine was limited to parts of three States—Louisiana, Florida, and Texas.

The Department in May 1933 removed the last of the Federal quarantines on sheep scabies. These quarantines at one time covered 2 million square miles in the Western States. The quarantines originally included North Dakota, South Dakota, Nebraska, Kansas, Texas, and all States west to the Pacific Ocean. Eleven of the States are now entirely free from sheep scabies. In most of the others in the range country there are only occasional cases, principally in feed lots where sheep come in from infected districts. The final eradication of isolated cases should not be difficult.

Investigations on the life cycle of horse bots showed the best time to treat horses and mules for the removal of these parasites. Essential facts with reference to poultry parasites, requisite to the formulation of control measures, were ascertained. Experiments developed a safe and satisfactory treatment for the removal of poultry ascarids.

Valuable New Disinfectant

As a further means of safeguarding livestock production the Department studied the chemical structure and effectiveness of various dips and disinfectants. The knowledge gained made it possible to standardize these products and make them more effective. Such studies recently led to the discovery that sodium orthophenylphenate is highly effective in destroying tubercle bacilli. The new germicide, which is now being made commercially, is especially suitable for use around dairy and farm buildings, since, unlike many other disinfectants, it has only a slight odor. It is readily soluble in water and is not severely poisonous to livestock.

Advances in Animal Husbandry

In animal-husbandry investigations the Department tested various promising means of producing livestock and their products more economically, while maintaining or improving their quality. Grazing investigations demonstrated that, while livestock do not produce so much from an acre of pasture as from an acre of harvested crops, pasture is the cheaper feed and returns the greater profit. Moreover, grazing conserves soil fertility better than when crops are harvested for sale or for livestock feeding. Other studies showed the high nutritive value of pasturage and the acceptable quality of meat pro-

duced wholly from grass-fed animals or those fed a combination of grass and grain. A much greater use of grass in the Nation's program of livestock production seems desirable.

Record-of-performance studies with cattle and with swine disclosed wide variations among animals of similar breeding as to feed utilization and quality of carcass and meat produced. Certain sires appear to be capable of transmitting a high degree of excellence both in feeding efficiency and quality of meat.

The Department assisted producers in improving methods of home butchering and the care of meat. The meat program now includes 45 States in which county, State, and Federal workers assist farmers in home curing large quantities of pork, beef, and lamb. In Texas home butchering of hogs has increased 50 percent during the last 2 years. It is now practiced on more than 75 percent of the half million farms of the State. In Georgia 15,000,000 pounds of pork are now cured under refrigeration by farmers, much of it in cooperative, farmer-owned storage plants.

New Basis for Poultry Improvement

Studies on the inheritance of egg production, which is the key to improvement of poultry flocks, yielded highly valuable results. The number of eggs laid by a bird does not indicate the ability of that bird to transmit high production to its female offspring. Nor does the egg production of the sire's dam serve as a dependable index of the breeding ability of the sire. The most reliable means that is readily available of judging the value of a sire for a laying flock is the average egg production of his daughters.

The investigations disproved some common assumptions on which poultrymen have been culling their flocks and furnished a more reliable system. Neither the shape of a hen's body nor the shape of her head bears any relation to her egg production. A hen's ability to lay depends on her breeding rather than on any so-called "egg-laying type." Investigators measured the live birds, the dressed carcasses, and the bones of about 400 hens whose daily egg production had been determined by trap nesting. They could find no relationship between egg production or egg size and the shape of the hen's body. Similarly, the shape of the head, often regarded as an indicator of laying capacity, was not a safe guide. Head and skull measurements revealed no factor associated with high capacity for egg production.

DAIRY RESEARCH

Experiments to determine the relative production of dairy cows on a ration consisting of roughages alone as compared with a full grain ration continue to show that cows, when receiving a good quality of hay, are capable of fairly high levels of production at economical costs, without the addition of other feeds to the ration. Twelve cows at the dairy field stations have now completed yearly records, during which time they received no feed but alfalfa hay. They averaged 11,399 pounds of milk and 405 pounds of butterfat on a mature basis. These same cows have made comparable records on a full grain ration, averaging 17,769 pounds of milk and 602 pounds of butterfat. Thus the rather extreme ration of alfalfa

hay alone produced 64 percent as much milk and 67 percent as much butterfat as did the full grain ration. These results, together with data showing the comparative cost of producing nutrients in the form of grains and hays, indicate that the farmer who grows all the feed for his livestock will make more money if he grows and feeds all of the ration in the form of roughage, even with the lower production from his cows. This appears to be a practical method of slowing up the production of dairy products and at the same time increasing the profits of the producer.

Dairy investigators studying the factors associated with loss of natural green color in hay found that artificially dried hay having a low moisture content lost but little color when stored in the absence of light and air, and that there was no excessive loss of color when the hay was exposed for 8 months in either diffused sunlight or air or both. The naturally cured hays possessed less color and more moisture and when stored in the absence of air at room temperature sustained a marked loss in color. Samples of both the artificially cured and the field-cured hays stored in a refrigerator for 8 months retained their color exceptionally well.

Feeding experiments at two field stations showed a slower percentage decline in milk yield when cows were receiving a ration composed entirely of grass silage than when they were receiving a ration consisting entirely of field-cured grass hay. Cows show a marked preference for grass hay or grass silage made from grass cut at an immature stage of growth. The yield of milk also was greater on hay or silage made from immature grass. Cows can consume sufficient grass in green form, or as hay, or as silage, when cut at the right stage of maturity, and properly cured or ensiled, to supply sufficient nutrients for maintenance and a yield of 35 to 45 pounds of milk per day.

Shortcomings of Certain Roughages

Data are accumulating which show that certain types of roughages are deficient in factors essential to normal growth and reproduction. In cows this is evident in failure to breed and eventually, if the ration is not corrected, in death. Young calves fed on milk from such cows fail to develop properly and invariably die with the characteristic evidences of a vitamin A deficiency. This condition may be corrected by the addition to the ration of cod-liver oil or other recognized source of vitamin A. After 6 months of age calves are much less sensitive to this deficiency. These results emphasize the importance of the quality of the roughage in the ration of the dairy cow not only in protecting the health of the cow but also in providing for human nutrition a milk suitable for infant feeding.

Alfalfa hay of good quality is superior to good grass hay and very much better than low-grade timothy hay for supplying vitamin A, and pasture is much better than any combination of dry feed. The effect of pasture on the vitamin content of the milk is marked and persists for some time after dry feeding has been resumed. The yellow color of the milk fat, which has been found to parallel the vitamin A content, is three times as high on pasture as on dry feed.

Economic conditions which tend to depress the prices of the major dairy products increase the necessity for turning the byproducts of

milk into income-producing channels. The most important constituents of these byproducts are lactose and casein. In the past year dairy research workers have devised a method by which a grade of lactose satisfactory for technical purposes can be made with 1 crystallization rather than the 2 ordinarily required. This process permits the use of multiple-effect vacuum pans for concentration, thus still further reducing the cost of manufacture. It is hoped that through lowered cost the use of lactose for technical purposes may be extended. The work on casein has shown that the difficulty encountered by paper coaters caused by foaming of the casein-clay mixture can be controlled by a minor adjustment in the method of making the casein. By complying with a few fundamental principles a casein suitable for all requirements can be made in this country.

As a part of a Swiss cheese quality-improvement program, a Department specialist in cooperation with the State of Wisconsin carried on intensive educational work at a limited number of factories. This work included efforts to bring about the delivery to the factories of milk that has certain desirable properties as determined by well-known methods, examination of the starters with a view to approving them or recommending changes, and studies of manufacturing methods and other problems pertaining to the successful operation of the factories. By comparing the grades of the cheese made at the cooperative factories where this intensive work was carried on in 1932 with those made at the same factories the preceding year, it was learned that over \$25,000 more was received for the cheese on account of the improvement in quality.

THE SOIL SURVEY

Results of the soil survey were utilized during the year in working out a basis for land classification in two States, the entire area of which had been surveyed. North Dakota used the soil survey as the basis for a comprehensive, exhaustive soil classification in a new land-valuation program designed to establish a fairer basis of taxation. The fundamental necessity for information supplied by the soil survey is obvious in connection with land classification, acreage retirements, and forestry, grazing, and other land-use problems.

The mapping of 27,771 square miles of agricultural lands in 29 States by the Bureau of Chemistry and Soils in the past fiscal year brought the total of land mapped and classified to date to more than 1,500,000 square miles or nearly a billion acres. The completed soil surveys of this vast area (greater than the combined area of Germany, France, and Great Britain) provide practical working maps and handbooks to assist many thousands of farmers in making the best use of their soils, and afford an inventory of national soil resources.

Study of the extremely fine portion of the soil known as the colloid showed that the plant-food storage capacity of the inorganic colloid in a soil depends not only upon its quantity but also upon its kind. This indicated that the colloid is the key to knowledge of the intrinsic fertility and behavior of great groups of soils. Data collected by the Department on the colloids of soils from all important farming regions of the United States will be of value in determining their proper utilization, whether for crops, for pasturage, or for forests.

FERTILIZER INVESTIGATIONS

Fertilizer manufacturers are adding magnesium to their fertilizer mixtures largely as a result of soil-fertility experiments in the Department and in State experiment stations. These studies showed that lack of available magnesium in some soils may seriously decrease potato yields. Small quantities of magnesium sulphate on certain soils in Virginia increased yields nearly 50 bushels an acre.

In certain soils investigators discovered zinc deficiency. An ordinary galvanized water bucket provided the clue. It enabled the Department's scientists to discover the cause and make notable progress in devising a cure for the rosette disease of pecans. Rosette first alarmed eastern growers of pecans and caused the abandonment of hundreds of acres of pecans in Florida, Georgia, and Alabama. As pecan orcharding spread westward to Mississippi, Louisiana, and Texas, the disease appeared in western groves and proved a serious problem that baffled State and Federal research workers, threatening a crop which in 1929 and 1930 had a farm value of approximately \$7,500,000 a year.

In the fall of 1931 when investigators were experimenting with dips and sprays as possible methods of control, galvanized-iron pails were used. By dipping rosetted leaves in a solution of iron sulphate they were able to prevent rosette on young leaves and to improve the condition of diseased leaves. Consequently they sprayed trees the next season with iron sulphate but were disappointed with results. Checking back on the analysis of the solution they had used successfully in 1931, the investigators discovered that zinc was one of several impurities present in small quantities. Then they recalled that when they had dipped the leaves a galvanized-iron pail had been used as a convenient container for the dip and conjectured that some of the zinc in the galvanic coating might have dissolved and displaced some of the iron in the solution. They tested solutions of zinc sulphate and solutions of the other impurities. The zinc sulphate solution was effective, the others were not. Zinc sulphate also has the merit of being a relatively cheap chemical, making it economically practical as a remedy.

Improvement in the eating and shipping quality of strawberries resulted from experiments on North Carolina soils typical of the strawberry-growing sections of the Middle Atlantic Coastal Plain. Fertilizers containing 6 percent nitrogen, 8 percent phosphoric acid, and 6 percent potash gave best results. Applications of quickly available nitrogen salts in the early spring gave berries with poor shipping qualities.

DEVELOPMENTS IN CROP UTILIZATION

The Department's ethylene treatment for coloring and softening fruit was carried out during the year for the first time on a commercial scale. Its use in softening pears for canning resulted in important savings. The average cost of sorting pears had formerly been between \$1 and \$2 a ton. The ethylene treatment, by uniformly softening the fruit, reduced this cost to less than 2 cents a ton.

At present most of the low-grade cull oranges are sold for less than cost of production and enter into direct competition with

higher grade fruit in the fresh-fruit market. Their conversion into orange juice will remove this cull fruit from the fresh-fruit market and extend the market for orange juice into locations less readily reached by fresh fruit. This is now feasible. Research in the Department showed that properly deaerated and flash-pasteurized orange juice will keep its fresh flavor for as long as 1 year under refrigeration at 35° F., and for shorter periods at ordinary temperatures. The addition of a small quantity of partly deterpenated orange oil enhances the flavor and extends the storage life of the product.

Work on fruit frozen under controlled conditions in the laboratory indicated a new approach to the detection of tree-frozen citrus fruit. Field experimentation when freezing weather strikes the citrus groves will determine whether this method can be applied practically. Immediate detection of frozen fruit, even before it leaves the groves, would be a double safeguard to the grower. It would prevent the cost of handling damaged fruit and the resultant demoralization of the fresh-fruit market and would enable the diversion of damaged fruit in bulk lots to byproducts plants for salvage before complete loss by spoilage.

About 40 American manufacturers are today making 80 different insecticidal products that contain rotenone or related products as a result of the Department's work showing the potency of rotenone as an insecticide and its complete harmlessness to man and domestic animals that may eat it.

The determination of the complete structural formula of rotenone last year by Department chemists and their present efforts to synthesize it are further steps toward its use as a substitute for lead arsenate in controlling the codling moth and other insect pests. The substitution of rotenone sprays for those of lead arsenate promises to save fruit growers the heavy cost of removing arsenical residues.

SOIL-EROSION STUDIES

Erosion studies at 10 regional erosion stations established facts in regard to the extent and rate of soil erosion, and developed methods of erosion control. Unrestrained soil erosion is rapidly building a wilderness of worn-out land in the United States. The wastage speeds up with the removal of the absorptive soil down to the less absorptive, more erosive subsoil. Approximately 35,000,000 acres of formerly cultivated land have been essentially destroyed for crop production; 100,000,000 acres of land now in crops have lost all or most of the topsoil; 125,000,000 acres of land now in crops are rapidly losing topsoil; and additional area is suffering from erosion in some degree.

Farmers operating on the 100,000,000 acres of denuded land are subsoil farmers, practicing bankrupt farming on bankrupt land whose productivity has been vastly reduced.

Methods of Erosion Prevention

Erosion varies enormously with soil character, slope, and rainfall. Thick-growing vegetation is one of the most powerful agencies of control. Practical measures call for extensive use of (1) trees and thick-growing vegetation, as grass, clovers, lespedeza, etc., on

the steeper slopes and the more erosive soils; (2) practice of those rotations which keep the land under the soil-saving crops a greater part of the time; (3) maintenance in the soil of a good supply of absorptive vegetable matter; (4) use of tillage operations that favor increased absorption of rain water, such as contour cultivation, scarification of the land, subsoiling (on some lands), and keeping the soil in as coarse physical condition as practicable; and (5) use of engineering structures, such as terraces and soil-saving dams. These are some of the fundamental facts about erosion which the Department's work and that of cooperating State agencies have established.

The significance of soil character in relation to the erosion problem can be illustrated by a single example. In 1931 red soil in the piedmont of North Carolina (one of the most extensive farm soils of the Southeast) lost 13 tons of soil an acre and 13 percent of the year's rainfall on a 10-percent slope, under cotton; whereas, the Shelby loam (the most extensive corn soil of northern Missouri and southeastern Iowa) lost 105 tons per acre and 28 percent of the rainfall on an 8-percent slope used for corn. The rainfall was about the same, yet the less steep highly erosive Corn Belt land lost eight times as much soil and more than twice as much of the rainfall. The practical information on the comparative erosivity of the most important soil types in each major agricultural region, gained from the Department's work at its 10 erosion stations, is highly valuable for the program of crop reduction by indicating how the land taken out of crop production can be protected from destructive erosion.

Soil-Erosion Control

Engineering investigations in the Department demonstrated the utility of broad-base terraces, level on permeable soils in regions of light rainfall but more generally with a longitudinal grade not exceeding 4 inches per 100 feet, and properly spaced. Tests on the soil-erosion experiment farms showed such terraces to be the most permanent and effective means of soil-erosion control for cultivated lands. They interfere little with the operation of farm machinery and hold the soil upon the fields for use of the crops. Only 2 to 5 percent as much soil is washed from the terraced areas on the experiment farms as from the similar unprotected lands. Some 15,000,000 acres of farm lands in the United States have been terraced during the past 15 years, largely in accordance with methods developed by Department engineers. The present rate of terracing is about 3,000,000 acres a year. Lands so badly gullied as to be abandoned for farming have been reclaimed by small dams of brush and poles, and within 3 years the fields have been plowed, planted, cultivated, and harvested, and the gullies practically obliterated.

FORESTRY

The developments of the last 6 months have given a tremendous stimulus to the forestry activities of the Department, and a new outlook on the future. This is partly due to the initiation of the emergency conservation work and the unexpected allotment of more than \$60,000,000 for land acquisition and for national-forest improvement and development work in addition to what the Civilian Con-

servation Corps is doing. It should be possible to accomplish within a short term of months what, as matters have gone in the past, could not have been completed within many years. Even more important is the prospect for comprehensively planned land use. Forestry and agriculture supplement and help each other and must be brought into a rationally adjusted balance that will make the most effective use, in the common interest, of the interlocking soil and water resources of the country as a whole.

The emergency conservation work was authorized by the Unemployment Relief Act, passed March 31. Three months later there were on the national forests 591 camps, each containing 200 previously unemployed young men from 18 to 25 years old who in the interval had been selected, assembled, made physically fit for work, and transported (in some cases 2,500 miles) to the designated locations. This was carried out under a Director of Emergency Conservation Work, with the Departments of Labor, War, Interior, and Agriculture cooperating.

On the national forests the Forest Service selected the projects and camp locations, provided work equipment and transportation, and supervised the field performance. It advised with and assisted the State authorities in planning and executing the emergency conservation work on State and private lands, except on parks, and had general supervision of this part of the undertaking. The number of these camps is 658.

The industrial recovery and public works legislation afforded a means of going still farther in providing for the improvement of the national forests.

Estimates of the Expenditures

Estimates of the expenditures which could be made to advantage within 2 years on projects that would qualify under section 202 of the act were prepared by the Forest Service and submitted to the Federal Employment Stabilization Board. The proposed transportation system will eventually require not less than 50,000 miles of road and some 45,000 miles of trail. For improvements other than roads and trails, the estimates for the 2 years aggregated \$27,172,015. From the public-works fund provided by the act there was made available for the fiscal year 1934, \$15,000,000 for forest highways, \$10,000,000 for forest roads, trails, bridges, and related projects, and \$15,982,745 for other classes of improvement, development, and protection work. The road and trail funds will be usable for maintenance costs as well as for new construction. Some additional funds are available under appropriation acts for the fiscal year 1934.

For more than 30 years the Government has been slowly equipping the forests with improvements necessary for protecting them, opening them up to full use, and putting their resources into better condition. When the western forests were first set aside they were merely great wilderness areas, without the most elementary requirements for their care and public use. Comprehensive and detailed improvement and development plans have long been prepared for every forest, to insure an orderly, if slow, advance. But the goal seemed indefinitely remote. Not only roads and trails were needed but also works of construction of a wide variety (lookout

towers, telephone lines, buildings, firebreaks, range fences, bridges, etc.), and such undertakings as reforestation, timber thinnings, and other cultural operations, range revegetation, measures to control insect epidemics, blister rust, rodent damage, erosion, and similar injurious factors, and resource and other surveys.

The Civilian Conservation Corps is busy on thousands of projects that embrace practically the whole field, even though the relatively brief period during which the corps will be available and other limitations inherent in the plan leave a vast deal more to be otherwise provided for. When in addition to what the corps is doing, the 2-year program now beginning to go forward through use of the National recovery funds is finished, the national forests will be greatly improved in their capacity for usefulness.

Supplementary Purchase Policy

The national forests, however, are an incomplete system. At first they could be created only where suitable public-domain lands happened to be available. They have never taken in all, even of these lands. Since 1911 there has been a supplementary purchase policy for building up national forests in the East. At the close of the last fiscal year the eastern part of the system comprised 42 units within which purchases were being made. Their gross area was not quite 15,270,000 acres, of which the Government owned a little less than one half. Progress had been brought to a standstill prior to March 4. By the Executive action which directed on May 20, that \$20,000,000 of the funds made available by the Unemployment Relief Act of March 31 be allotted to this Department for additional land purchases for national-forest purposes, as a means of broadening the field for employing effectively the Civilian Conservation Corps, the whole situation was changed.

Up to September 1, the National Forest Reservation Commission had authorized purchases to a total of more than 940,000 acres of land, in 30 of the established purchase units, at a total cost of \$1,763,964. This acreage is approximately one fifth as much as the total of the preceding 22 years since purchases began, and is almost twice the total in any previous full fiscal year. The Commission also approved the establishment of 13 new units, and extensive additions to a number of the old units, thus broadening the scope of the acquisition program by about 6,000,000 acres. This is a forward step of profound significance.

The national welfare demands a much broader Federal conservation program than that of the past to correct the manifold evil consequences of unchecked individualism in the handling of forest resources and to promote a properly balanced and efficient land use. The readjustments essential to the rehabilitation of agriculture will add materially to the area available for forestry. Private ownership of forest land is breaking down on a scale only partly indicated by the alarming spread of tax delinquency and land abandonment in many States, following removal of the timber growth. Current methods of forest utilization and the lack of adequate fire control have been adding rapidly to the area of idle land, and in addition have been working progressive deterioration in the stands and productive value of by far the greater part of the privately owned for-

ests not yet near abandonment. A great national effort is called for to stem the tide now running strongly in the direction of impaired forest resources and diminished opportunities for remunerative labor in connection with their use and perpetuation.

National Plan for the Forests

On March 27 this Department submitted to the United States Senate a report of the Forest Service prepared in response to Senate Resolution 175 (72d Cong., 1st sess.) and presenting A National Plan for American Forestry. The report stated:

The Department fully endorses the conclusions reached, that public agencies should acquire 224 million acres of forest land, including a part of the agricultural land now available, and place it under management at the earliest possible date following acquisition. A considerable part of this land has or will come into public ownership anyway by reason of tax delinquency. The States and their local subdivisions should take over as much of this acquisition program as their resources permit * * *. It is believed that the resources of the States will be fully taxed to acquire and manage 90 million acres leaving 134 million acres for the Federal Government.

The proposed plan, however, went farther than the program of public-forest ownership and administration thus briefly indicated. It contemplated assumption by the private owner, with suitable public help, of a very substantial part of the national undertaking to obtain all of the benefits, economic and social, which the forest resources of the country are able to render under a wisely devised and rightly applied plan for their best use. The code for the lumber industry adopted under the National Recovery Act appears to open the door widely for an extremely important change in this part of the field, if the right kind of industrial leadership and action, together with public cooperation to the extent necessary, are forthcoming.

The code declares as one of its purposes "to conserve forest resources and bring about the sustained production thereof"; and the applicant industries have undertaken, "in cooperation with the public and other agencies, to carry out such practicable measures as may be necessary" to this end. But if the end is to be attained, a liberal Federal contribution must be made. Both a great public opportunity and a great challenge to public action are involved which must be met promptly and vigorously.

Regulated grazing on the national forests not only has conserved and in many cases increased the carrying capacity of the ranges but also has contributed markedly to stabilization of the western range livestock industry and to better and more profitable practices of livestock management. The grazing privilege is eagerly sought by large numbers of outside livestock growers for whom there is no room. The departmental policy has always aimed at a scale of charges for range use that would obtain a fair and reasonable return for the privilege, while protecting the industry and the individual users against unstabilizing forces and competitive pressure for the ranges. The primary objective has been to make the resource contribute to healthy economic and social conditions in the dependent communities and regions.

This has precluded a policy of opening the range to competitive bidding. However, rental values of comparable range lands in the same neighborhood have in the past been the basic guide in establish-

ing the fee schedule. Extreme drought conditions in the West in the summer of 1931 and a very severe following winter warranted a 50-percent reduction in the 1932 grazing fees, as an emergency-relief measure, and deferred payment was allowed to December 1 in place of the usual advance payment. Last winter and spring range users pressed for a continuance of the reduction. The Forest Service studied the practicability of relating the fee to the market prices of livestock.

Recommendations approved on May 27 provided for a yearly adjustment of the basic rate in accordance with changes in the average price received by livestock producers in the 11 Western States. The amount of the adjustment will be determined by the ratio that this average price bears to the corresponding average price during the period 1921-32, inclusive, for cattle, and during the period 1921-30, inclusive, for sheep. The base rate to which the adjustment applies is the average national-forest fee in effect during 1931, which was 14.5 cents per head per month for cattle and 4.5 cents per head per month for sheep. The adjustment will be made for each year by raising or lowering this base rate in the same ratio that the average price of livestock for the preceding year bears to the specified periods. It has been applied to the present grazing season and has lowered the average cattle fees 37.6 percent and sheep fees 54 percent.

IRRIGATION AND DRAINAGE STUDIES

Profitable agriculture in a large part of the West depends upon irrigation, and for many years the Department has studied the economical use of irrigation water. Irrigation requirements involve the settlement of water-rights claims; the equitable apportionment of public water supplies; the engineering determination of the capacities of canals, reservoirs, and other irrigation works; the prevention of waste in the distribution and use of the water; and the determination of the area that can be irrigated from a known water supply.

All reliable data that could be obtained have been assembled relating to experiments in the water requirements of crops. Average irrigation requirements have been determined for 97 subdivisions in the 5 regions that comprise all that part of the United States west of the one-hundredth meridian. Publication of the results should benefit not only farmers but also legal, administrative, and engineering agencies concerned with the proper use of water in the irrigated areas of the West.

Land Drainage

Many drainage districts rated as financially sound under what were considered normal economic conditions cannot meet their financial obligations because of tax delinquencies. This condition threatens the landowners in those districts with loss of their farms and discourages efforts on their part to make even partial payments to the holders of the obligations. In order to avoid complete loss of the investment, landowners and bondholders must cooperate in adopting plans for rehabilitation based on the earning power of the lands. Mutual sacrifice is necessary. Engineers in the Department worked out one method by which such financial difficulties could be

settled in a plan of rehabilitation for one of the largest drainage districts in the United States. The drainage taxes to be paid by the landowners each year would be based on the crop yields and the prices received for farm products. Maintenance of the drainage works, in order to conserve the earning power of the lands, would be provided before determination of the amount available for payment on the bonds, and that amount would be accepted in full for the bonds due that year.

COTTON GINNING AND FARM MACHINERY

In order that the full inherent quality of the cotton crop harvested may be obtained by the growers, cotton must be properly conditioned and ginned. At the cotton-ginning laboratory of the Department, improvements in the design of seed-cotton driers have been made that simplify the construction and reduce the cost of these machines, besides increasing their effectiveness in conditioning the cotton for ginning. Some 45,000 bales of cotton were conditioned last season in commercial driers, using the process patented by the Department. The value of that cotton was enhanced 60 cents to \$5 per bale above the cost of drying. Experiments showed, however, that the ill effects of rough harvesting methods cannot be entirely overcome by the conditioning and cleaning machinery now available.

The Department recently designed and constructed a combination planter and fertilizer distributor, with which experiments in fertilizer placement can be extended to include snap beans on bedded fields. A trash guide of new design was developed for corn-borer-control work. This covers crop debris with smaller plows than were effective previously. Improvements in methods of artificially drying freshly harvested rice, particularly by establishing proper temperatures and exposure periods, greatly reduced the cost of drying and at the same time bettered the quality of the product. A variable-depth attachment for cotton planters, developed to place the seed regularly from minimum to maximum planting depths, was covered by public patent. In many comparisons with uniform-depth planters, during two seasons, this device largely eliminated the necessity for replanting, and materially better yields were obtained. Manufacturers are adapting the variable-depth principle to planters for some truck crops.

INSECT-PEST CONDITIONS AND CONTROL

The grasshopper plague in the northwestern Plains States, which caused such heavy destruction of crops in 1931 and 1932, continued during the present season (1933), being especially severe throughout much of North Dakota and extending southward into central and eastern South Dakota, northeastern Nebraska, and westward over eastern and northern Montana, with isolated or less severe infestations in some half dozen other Western States. In general this situation closely paralleled the predictions from the egg surveys made in the fall of 1932.

The outbreak of the last three seasons in the Plains States is unprecedented as to area and continuance and resulted from a gradual building up during 2 or 3 favorable years prior to 1931 of common types of Plains grasshoppers. In Minnesota and North Dakota

grain and other crops were given very material protection by extended use of poison bait. Minnesota furnished bait to the cost of nearly a quarter of a million dollars for use of farmers, and from State, county, and other sources some \$80,000 was similarly expended in North Dakota. The benefits of the fairly adequate use of baits in Minnesota in 1932 were reflected in 1933 in the great diminution of area in which grasshoppers occurred in destructive numbers. In North Dakota the control was not sufficient to prevent extended egg laying in the fall of 1932, and this was reflected in wide-spread grasshopper damage in that State the present season.

Mormon Cricket

The Mormon cricket, outbreaks of which have been effectively controlled in recent years, assumed a threatening status on the Fort Hall Indian Reservation in eastern Idaho in 1932 which, though fairly well controlled, carried over into 1933. By pooling the resources of the Indian Service together with the assistance authorized by this Department in the purchase of calcium arsenate and dust guns, a control campaign was carried out in cooperation with State agencies which prevented crop losses. The appearance of this insect, however, in other isolated areas in Idaho and its reappearance in northwestern Colorado indicates that trouble from it may again be expected next season.

Bollweevil

In the spring of 1933 the bollweevil outlook threatened heavy crop damage on the basis of the unusually large number of weevils entering hibernation in the fall of 1932 and the very considerable weevil survival, though small in percentage, into the spring of 1933. The excessive drought and heat in June and July over much of the cotton area greatly checked weevil development, and serious infestation has been spotted and limited to areas of more or less localized rains. A biological factor of much interest in relation to the weevil is the definite determination this season that a malvaceous plant, althea (*Hibiscus syriacus* L.), widely used in the South as a hedge plant and ornamental, may serve as a host of the weevil.

Pink-Bollworm Eradication

Measures directed against the pink bollworm in Texas, New Mexico, and Arizona, were highly successful in both the eastern and western sections of the formerly infested area. In the Salt River Valley of Arizona, no pink bollworms have been found since the 1931 crop. It was possible in September 1932 to remove the fumigation requirement that had been maintained as a condition for the interstate shipment of cotton from that valley. The insect was also eliminated from seven counties of western Texas adjoining the southeastern portion of New Mexico. These counties were entirely released from quarantine regulation in the spring of 1933. Outside of Florida, the known pink-bollworm infestations in this country are now confined to the limited irrigated sections between the Pecos Valley of western Texas and the Safford Valley of Arizona.

Surveys around the Florida outbreak of the pink bollworm showed the presence of the insect in a few cotton fields in the northern part

of the State in Alachua and Columbia Counties, in addition to the infested wild cotton of the southern section of the State. A vigorous eradication program is now under way using substantially the same methods that have been successful elsewhere. The Florida infestation is largely confined to wild cotton on the keys and along the Atlantic and Gulf coasts of the southern part of the peninsula. Infestation in wild cotton extended up the west coast from Naples to Tampa Bay, which is within 150 miles of commercial plantings. The wild cotton north of Naples has been eradicated, and excellent progress has been made in destroying the wild cotton in the southern part of the State and on the keys. Destruction of this wild cotton is important for the protection of the main Cotton Belt of the United States lying several hundred miles to the north. If an infestation in the wild cotton on the keys and in the southern part of the peninsula were allowed to persist indefinitely, the Cotton Belt could probably not be permanently protected.

The section which is subject to the heaviest damage from the pink bollworm is the Big Bend area of Texas. An energetic clean-up program was carried on in that area during the past winter to reduce the heavy infestation and limit the risk of its spreading.

The roller method of sterilizing cotton lint to prevent the spread of the pink bollworm was developed and applied commercially during the year. The operating cost of applying this treatment is 1 cent per bale, as compared to a cost of \$1.25 to \$2 per bale for fumigation, or \$0.75 to \$1 per bale for compression.

Beet Leaf Hopper

The growers of sugar beets in the important southern Idaho district centering at Twin Falls have come to have full confidence in determining their plantings on the basis of the predictions of the Department specialists on the type and volume of migration of the beet leaf hopper to be anticipated from the wild areas of winter hibernation and early season breeding. The studies of the pest have determined its migration in the fall to these wild areas and its breeding up in such areas to return, following the drying up of natural food plants in early summer, to the irrigated areas. Predictions of probable abundance or scarcity of leaf hoppers have now been correct over a period of 7 years, with the single exception of 1930. In that year the important migration came from an area in the Northwest from which no migration had previously been determined. The surroundings of this Idaho district are now fully covered by the annual fall and spring surveys, and the correctness of the warnings issued have been notable in the last 3 years (1931-33).

In the important beet-growing districts in the San Joaquin-Sacramento Valleys of California, similar studies of migration and breeding of these leaf hoppers have been made. In the last 2 years in these districts, a very promising type of control has been secured by spraying the leaf hoppers following their fall migration and concentration for the most part in grassy valleys or canyons surrounding the irrigated district. Such control has been carried out under the direction of this Department, following its initiation by important interests engaged in the production of beets and the manufacture of sugar.

Mosquito Control and Unemployment

The importance of mosquitoes as pests and as carriers of diseases of man and animals has made necessary the investigations of the habits and means of control of the many species involved. Drainage is one of the most effective and generally applicable methods of control. It is desirable to apply work relief to projects which will yield distinct public benefits, and therefore the possibility of utilizing the unemployed in drainage operations received early consideration. In such work a very large percentage of the funds expended go to hand labor. This fact, and the immediate, widespread and relatively permanent benefits derived from mosquito control, together with the proximity of serious mosquito conditions to centers of population where unemployed problems exist, highly commend this work. Some cooperative surveys of mosquito problems have been undertaken. Several States have made rapid progress in draining vast salt-marsh areas where myriads of mosquitoes have been produced heretofore.

Spotted-Fever Tick

The occurrence of the deadly disease of man known as Rocky Mountain spotted fever in the Eastern States has naturally focused attention on the ticks which transmit it. The American dog tick is the carrier of the disease in the eastern half of the country. This dreaded malady has appeared in nearly every State; hence the problem is truly a national one. Methods of reducing the dangers of infection have been developed as a result of investigations of the tick concerned. These consist of steps to avoid the attachment of the tick to man and the reduction of the tick population near habitations. It is important to prevent engorgement of the adult ticks on dogs and horses. This may be done effectively by applying certain insecticides, especially derris powder. The immature ticks develop on small wild rodents, such as field mice, hence the destruction of these animals is indicated, especially by exposing them to the attacks of birds and animals of prey. This can be accomplished by clearing out underbrush, tall grass, and weeds near homes and camps. The utilization of the unemployed in this work has been recommended to communities where the disease occurs.

European Corn Borer and Phony Peach Disease

Two domestic plant quarantines, one relating to the European corn borer and the other to the phony peach disease, were revoked during the year.

The lifting of the European corn-borer quarantine was necessitated by lack of available funds for its adequate enforcement. This action was promptly followed by the issuance of State quarantines by some 27 States against the 13 infested States. These State quarantines restricted shipments to a considerably greater extent than was the case under the Federal quarantine and threatened serious interference with the movement of corn and certain other host plants of the borer out of the infested area. The difficulty was solved by the inclusion in the Agricultural Appropriation Act of an item for the certification of such products to meet the requirements of State quarantines, and a Federal inspection service was

set up in March to supply the demand for this type of certification. This action establishes a precedent in dealing with domestic plant quarantine problems and is a distinctly forward step in the prevention of spread of plant pests, without undue hardship to the general public.

The anticipated heavy increase in damage by the European corn borer in the Great Lakes region did not develop. Such increase of population and damage was predicated on the unusually heavy larval populations successfully passing the winter in cornfields. However, unfavorable spring and early summer conditions so delayed planting and development of the corn in this one-generation area that when the moths emerged, the corn was too small to be attractive. In addition to this, the egg-laying period coincided with unusually hot and dry weather, resulting in the killing of many of the egg masses shortly after deposition. The field counts to determine the actual status of corn-borer population will not be available until October, but the indications point to no increase in this area.

The phony-peach-disease quarantine was canceled in March, as the discovery that the disease occurred over much more extensive areas in the South than had previously been known indicated that its further spread could be handled more satisfactorily by improved and modified nursery inspections in the various States than by the enforcement of a Federal quarantine. Department investigations point strongly to the peach borer as the carrier of the disease, and the prevention of spread of infection will now be undertaken by the various States through the inspection of the environs of peach-growing nurseries and the elimination of peach-borer infested or injured stock. The Department will continue to aid in the eradication of the disease and in the development and adoption of improved culling practices by the various State nursery inspectors.

Insecticide Residues

The presence of excessive amounts of spray residue found on deciduous fruits and vegetables moving interstate, and the increasing demand of consumers that such products be free from harmful residues placed added emphasis on the problem of controlling insects attacking deciduous fruits and vegetables. It stressed the need of using methods or materials that would eliminate or reduce injurious residues on the product when it appeared on the market. The Department reviewed the standard methods used for the control of insects attacking deciduous fruits and vegetables and issued circulars containing recommendations for the control of a number of important pests. The revised recommendations placed special emphasis on the time and method of applying insecticides and urged the use of supplementary controls such as sanitary and cultural practices. Revised schedules for the control of insects on vegetables and small fruits, such as strawberries and blackberries, eliminated the use of arsenate of lead and restricted the other arsenicals to plants in such stages of growth that they do not reach the market.

For the control of insects attacking deciduous fruits it was recommended that the use of arsenate of lead be restricted as far as possible. For the control of the grape berry moth, the most important pest of the grapes produced in the eastern area, it was recommended that calcium arsenate be substituted for lead arsenate. The spray

schedules for the control of the codling moth suggested the use of calcium arsenate with lime and a sticker or nicotine sulphate and mineral oil during the latter part of the season and, where many sprays were necessary, emphasized adequate washing prior to consumption or marketing.

DIET INVESTIGATIONS

Plans for adjusting agricultural production to consumption should include the utilization of foodstuffs by the family in the home, which, after all, is the part that means most to social welfare. Although we may now be the best-fed nation on earth, despite various shortcomings, yet there is still much room for improvement. We can practically wipe out rickets, pellagra, and other ills that come from faulty nutrition. We can build up the national health through better food habits and prevent many diseases which are hastened if not actually caused by wrong choice of food. The goal is optimum nutrition.

The first step is to produce the right kinds and the right quantities of foods so that people on farms and people in cities may have a well-balanced diet. At the same time the Nation must have facts about diet in relation to health, the standards of good nutrition, and the guiding principles in selecting a diet that promotes and safeguards health. Families need information on how to get such a diet with the amount of money they have to spend for food.

This year the home economists of the Department finished drafting master diet plans to furnish such a guide. These plans translate the scientific facts on food values and nutrition into specific quantities of foods on a two-way basis, nutritive content and cost.

Four typical diets at four levels of cost are included: A liberal diet when there is plenty of money to spend on food; a moderate-cost adequate diet; a minimum-cost adequate diet; and a restricted diet only for emergency use, such as relief agencies in many localities were forced to follow during the economic crisis. Some relief agencies, fortunately, were able to hold to the next higher standard, the adequate diet at minimum cost which provides a wider margin of safety, and this the Department counseled them to do wherever possible.

Each of these plans gives the quantity of foods needed yearly per capita on the basis of our population according to the 1930 census. Starting with pounds of flour and cereals and quarts of milk, the list gives definite quantities for each group of foods as delivered to the consumer's door. For example, on flour and cereals it runs: Liberal diet, 100 pounds; moderate-cost adequate diet, 160 pounds; minimum-cost adequate diet, 224 pounds; restricted diet for emergency use, 240 pounds. Incidentally, this brings out also the important place the cereals fill in the lower cost diets.

In these per capita figures little allowance could be made for waste by the consumer or wastes in distribution. Waste in the kitchen is very difficult to estimate. What one household considers thrift another calls willful waste, and beyond question much good food is thrown away in public eating places. In converting these per capita figures into crop-production guides, suitable margins must be added to cover losses in harvesting and grading, deterioration in transportation and storage, and so on to final retail distribution.

Needs of Individuals and Families

Next, these pattern diets break down into quantities of foods for individuals and for families of different make-up. The nutrition experts find that, after 4 years of age and through adolescence, boys and girls need different quantities of food. An active growing boy generally needs the most food when he is 15 to 18 and a girl when she is 13 to 16. The boy in his teens has a right, it seems, to eat the family out of house and home. Adults differ also in their food needs depending on whether they are men or women and whether they have indoor jobs or do strenuous out-of-door work. These diet plans recognize all these widely different food needs of persons from babyhood to adult age and work them out in terms of pounds, quarts, and dozens of standard foodstuffs. So practical and so definite is the information that an extension worker can sit down with a farmer and his wife and help them make out a food budget for the year ahead, telling exactly how much of each kind of food they need to grow at home and how much they will have to buy in order to keep the family well nourished. Or a social-welfare worker advising a group of city women can help them draw up market lists to suit their incomes, never forgetting what this food means to family health.

Figured on the basis of 1931-32 retail prices, these four pattern diets range from \$61 to \$165 per capita per year. Or, worked out another way, it took, on the 1931-32 price level, \$79 to buy a restricted emergency diet for a very active man and \$215 to provide him a liberal diet. The minimum-cost and the moderate-cost adequate diets fall in between. The constant shifts in food prices make these cost figures of value only for purposes of comparison. Furthermore, they do not allow for the personal element in buying. Some housekeepers are shrewder shoppers than others. Given the same sum of money and the same market list probably no two women would go out in a city market and buy exactly the same foods. So when the food economists fix an average price on a diet, they do not expect it to be taken too literally. Some shoppers will beat the average and get more for their money; others will always fail to pick up the bargains.

The lowest diet is included only for emergency use, as during the years when unemployment took many families down to bedrock and below. It is not what dietitians would ever recommend from choice. But it does show how to lay out a meager amount of food money to get the greatest return in nutritive value. It represents quantities of food, especially protective foods rich in minerals and vitamins, below which no diet can safely fall. Relief workers and others cooperating in this plan for a low-cost diet helped many families to weather the crisis without permanent damage to health. The adequate diets at minimum and moderate cost recommend freer use of milk, vegetables, fruits, lean meats, and eggs. They appeal more to the appetite, and they furnish a generous margin of safety on the nutritive side. The liberal diet at the top of the scale will promote better-than-average nutrition.

In cities many families of skilled wage earners and well-to-do business and professional men spend enough money to serve this liberal diet on their tables regularly, but probably relatively few

select food which has so high a nutritive value. Certainly far too few farm families have food that reaches this high level. A survey of a group of farm and village families in what is normally a prosperous part of central New York State showed that while their food had a money value somewhere between the minimum- and moderate-cost adequate diet mentioned, the diets of more than two thirds of the families were not adequate nutritionally as judged by our present standards.

GAME CONSERVATION

Critical conditions exist in waterfowl-breeding areas in the north-western part of the United States and in the prairie Provinces of Canada. The numbers of the birds, vastly important for food and as a recreational resource, have been reduced by severe droughts, land settlement, and steadily increasing pressure from hunting throughout their ranges. Hundreds of observers from the Arctic Ocean to the Mexican border made reports to the Bureau of Biological Survey on local situations. At 50 bird-banding stations supervised by the Bureau, more than 31,000 ducks and geese were banded to determine accurately their principal stopping points and their routes of travel. Biologists in the Department studied conditions during both the southward and northward migrations, and on the chief winter-concentration and feeding areas of the birds. The information thus obtained afforded a basis for regulations governing the protection of waterfowl and the hunting privileges that may be permitted under the Migratory Bird Treaty Act.

Following the droughts of 1929 and 1930 observers noted that eelgrass, an important salt-water food for wild fowl, was seriously affected throughout its entire American range and was disappearing. That the cause was not directly traceable to the drought was shown by available records of similar trouble in other parts of the world. Drought conditions, however, by altering the saline content of the water supporting stands of eelgrass, probably favored the destructive agent, which is probably a bacterial disease. Eelgrass normally is the most important food plant of the brant and to a considerable extent of certain other wild fowl and is utilized also as an article of commerce. The greatly reduced supply was accompanied by an alarming decrease in the numbers of brant, estimated in some localities to be as much as 90 percent. As a result of these findings, the brant on the Atlantic coast are given complete legal protection during the coming year, by amendments to the regulations under the Migratory Bird Treaty Act.

Migratory Bird Refuges

On May 29 the President approved the establishment of Civilian Conservation Corps camps at the Blackwater Migratory Bird Refuge, Md., the Swanquarter Migratory Bird Refuge, N.C., and the St. Marks Migratory Bird Refuge, Fla. These refuges were acquired by the Department under the Migratory Bird Conservation Act of 1929 and have been under administration of the Bureau of Biological Survey for about 2 years. With the aid of the Conservation Corps extensive developments at each refuge will include

the construction of roads, trails, fire lines, and look-out towers, and of dams to create fresh-water ponds for wild-fowl food production. These improvements will greatly facilitate the administration of the several areas and materially improve their value in wild-life conservation.

In the 4 years since the Migratory Bird Conservation Act went into effect the Migratory Bird Conservation Commission has authorized the Department to acquire by purchase 137,664 acres for refuge purposes. Throughout the 48 States 141 proposed refuge sites, aggregating 3,710,927 acres, have been examined and appraised by the Bureau of Biological Survey under the provisions of the act, and 22 refuges have been created in 17 States and Alaska, at an average cost for lands purchased and in process of purchase of \$4.57 per acre. There also have been taken 936,687 acres by Executive order, 2,033 by gift, 12 by act of Congress, 1,944 by lease without option to buy, and 6,343 by cession, bringing the total to 1,084,683 acres. The increase of 830,130 over the acreage under jurisdiction last year is largely through the establishment of the Boulder Canyon Wild Life Refuge of 659,130 acres, superimposed on the area for the development of the Boulder Canyon water power project, and the withdrawal of 135,184 acres of public lands in central Nevada, where additional studies will be made to determine their ultimate refuge value through the development of water resources. Progress on establishing the Cheyenne Bottoms Migratory Bird Refuge, Kans., has ceased for lack of appropriations to carry out the intent of the act authorizing it.

Fur Farming

American fox farmers harvested 150,000 silver-fox skins during the season 1933 and disposed of the bulk of them at prices that under prevailing conditions were considered very fair. An early European demand for American silver-fox skins saved marketing boards and auction companies from disposing of pelts at ruinous prices. Financially the fur-farming industry has been in good shape and the average fur farmer has had no heavy encumbrances. Bank closings, however, created problems in financing the feeding and care of the young foxes that were to provide this year's crop of fur. The Bureau of Biological Survey assisted fox farmers and their organizations in presenting their case to governmental agencies as an enterprise deserving financial aid to carry them over the critical period.

A general wave of buying during June and July advanced prices on the fur markets as much as 60 percent, the average being about 25 percent. Shippers and dealers were more optimistic than in 1932. The fur industry caught up on some of its back indebtedness and liquidated large quantities of skins at a profit.

AGRICULTURAL EXPERIMENT STATIONS

The Department, through its Office of Experiment Stations, administers the Federal funds appropriated for the State agricultural experiment stations and for the experiment stations in Alaska, Hawaii, and Puerto Rico. During the fiscal year ended June 30, 1933, the Federal funds involved included \$4,320,000 for the State experiment stations and for the experiment stations in Alaska, \$64,000 to Hawaii, and \$78,560 to Puerto Rico, or a total of \$4,477,560.

The Department coordinates its work with that of the experiment stations to prevent unnecessary duplication and to adapt it to the varying conditions and needs of the several States and Territories, as well as to the Nation as a whole. More than 1,000 formal projects and a number of informal undertakings are now in progress, with a steady improvement in the cooperative work and relationships. The experiment stations necessarily have to deal with a wide range of local conditions, needs, and problems. They have an exceptional opportunity to extend and make more effective the work of the Department as a national research agency. Some recently reported examples of station work will show that the experiment stations, while highly responsive to local needs and problems, are also alive to the larger questions of national policy.

Soil Surveys in Forestry

Illinois has plans well under way for two national-forest units involving 599,232 acres in southern Illinois. These plans would be less advanced but for the soil survey. Facts collected in the survey were used for blocking out the two units. If these national-forest units materialize, they will be included in the national reforestation program and will employ hundreds of men. They will take thousands of acres of marginal and submarginal land out of production. This will relieve the counties and the State of maintaining roads and schools in the area. The money that the counties will receive from the forests will far exceed what they would have realized from taxes.

New Uses for Idle Acres

Reduction of farming in Massachusetts has resulted in many idle acres. Although a considerable amount of the area may be taken up for part-time farming, recreation, and residential uses, the major part must be utilized for the growth of trees. The Massachusetts Agricultural Experiment Station urges increased use of the lands for recreation and forestry. Much of the idle land is well suited for pasture. Stony upland pastures, the Experiment Station has shown, can be profitably improved with a relatively small outlay for fertilizers.

Revising Taxation Systems

Results of considerable social and economic importance resulted from taxation studies reported by the South Carolina Agricultural Experiment Station. These studies furnished the basis for discussion of tax reform during the 1933 session of the State Legislature. Farmers as a group are overtaxed. Until these studies were made, however, there was no basis, as far as South Carolina was concerned, for proper legislation. The findings of the Station, it is believed, will bring about a reorganization of the system of taxation to the advantage of the State and of its farmers. The Louisiana Experiment Station made a study of taxation in that State, which it is believed will serve as a guide in revising the tax system. Research by the Pennsylvania Station furnished the basis for a proposed revision of tax laws.

Improving the Quality of Cotton

South Carolina and other Southeastern States until recently failed to produce cotton of the quality demanded by the mills. A survey by the State experiment station showed that the mill requirement is largely for cotton fiber ranging from $\frac{1}{8}$ to $1\frac{1}{8}$ inches in length, but that the mills were able to get only about one fourth of their needs in the State. Through variety tests, fiber studies, and spinning tests the Station showed that cotton of the desired quality could be produced in any part of the State at no greater cost than the short stapled, poorer quality, commonly grown. As a result of recommendations based on these findings, the production of cotton of the staple lengths desired increased from 38 percent of the total crop in 1928 to 75 percent of the crop grown in 1932. This change represented, even at depression prices, an increased income to the farmers of the State of more than \$600,000 annually. The mills are now getting, nearby, practically all the cotton they need of the staple lengths mentioned.

Mineralized Milk

Milk is widely recognized as more nearly a complete food than any other single item common in the feed of animals or in the diet of human beings, but it has never been possible to rear experimental animals from weaning to maturity on cow's milk alone. After a few weeks on an exclusive milk ration, the animals lose in weight and die of anemia. The inability of milk to produce the necessary hemoglobin in blood has been attributed to its low iron content. The Wisconsin Experiment Station demonstrated that milk is deficient also in copper and that copper is indispensable in the nutrition of mammals. It is required as a supplement to iron in the formation of hemoglobin, and adding inorganic iron and copper salts to milk will prevent anemia. The station proved also that the addition of traces of manganese to a diet of cow's whole milk supplemented with iron and copper had a favorable effect on growth and reproduction. Pigs made greater growth on the mineralized milk alone than on a standard mixed ration, and rats grew and reproduced normally through four generations on an exclusive diet of mineralized milk.

Snow Surveys for Forecasting Water Supply

The amount of snow on the mountains is a matter of the greatest concern to farmers and stockmen, as well as to municipalities and power plants, in regions of deficient rainfall, because it is the measure of the water supply for the coming season. Snow-survey methods perfected by the Nevada and Utah Experiment Stations furnish a practicable means of measuring the snow cover and predicting the available water supply. The high watersheds of Utah are covered with a network of snow-survey courses, which serve as a basis for determining the run-off for each watershed and forecasting the stream flow. Wide practical application for this purpose has been made of the snow-cover survey methods.

FOOD AND DRUGS ACT

The original purpose of Congress in enacting the Federal Food and Drugs Act, namely, to safeguard the consumer against the sale of adulterated and misbranded foods and drugs and thus to protect the public health and pocketbook, has never been altered. But, for more than 15 years, Department officials have recognized that the law has definite limitations. It does not take into sufficient account the vast change in conditions which has come about in the food and drug manufacturing industries since the law was passed in June 1906. The Department has repeatedly advocated legislation to bolster up the weak points.

The Department's urge for a strengthened bill culminated, during the fiscal year, in the introduction in Congress of a completely new food and drug law designed to supplant the existing measure. This bill, Senate 1944, introduced by Senator Royal S. Copeland of New York on June 12, was prepared in the Department of Agriculture by direction of the President and with the active cooperation of the Secretary and the Assistant Secretary of Agriculture. Before it was introduced, the measure received the approval of the Department of Justice. It preserves all of the good features of the present law.

Among other things the new bill contains the following provisions:

Cosmetics, hitherto not covered by the Food and Drugs Act, are brought under regulatory authority.

Mechanical devices intended for curative purposes, and devices and preparations intended to bring about changes in the structure of the body are included.

False advertising of foods, drugs, and cosmetics is prohibited. The average consumer is guided far more by claims made in advertising copy than by the necessarily modest declarations printed upon labels of goods shipped in interstate trade.

Definitely informative labeling is required. The present law, insofar as labeling requirements are concerned, is very largely negative. It specifies that labels must be truthful but requires a minimum of information.

A drug which is, or may be, dangerous to health under the conditions of use prescribed in its labeling is classed as adulterated, and therefore illegal. This provision will prevent the indiscriminate marketing of drugs which should be administered only under careful supervision and control.

Promulgation of definitions and standards for foods which will have the force and effect of law is authorized. Without such standards it is extremely difficult for the Government to establish in court, before a lay jury, violations involving adulteration or misbranding of foods.

The prohibition of added poisons in foods, or the establishment of safe tolerances thereof, is provided for. Many food plants may at one stage or another in their growth develop or be contaminated with poisonous substances. Where the presence of poisons is unavoidable, the quantities of the injurious ingredients must be kept so low that by no possibility will the food be harmful. Under the new bill the Secretary will have authority to establish safe tolerances for injurious ingredients and to prohibit interstate traffic in foods which contain poisons in quantities exceeding the tolerances.

The operation of factories under a Federal permit is provided where protection of the public health cannot otherwise be effected.

More effective methods are provided for the control of false labeling and advertising of drug products.

More severe penalties for violations, as well as injunctions in the case of repeated offenses, are prescribed. The low penalties provided in the present act are inadequate to check first or repeated offenses.

Enforcement of the Law

Enforcement of the Federal Food and Drugs Act necessitated the initiation during the year of almost 3,000 legal actions against adulterated or misbranded foods and drugs, or their manufacturers. As in the past, the Food and Drug Administration concentrated its efforts on offenses involving public health. The Administration continued to devote from one fourth to one third of its appropriations to the control of interstate shipments of fresh fruits and vegetables found to carry residues of poisonous sprays, such as lead and arsenicals. Two hundred and forty-one seizures of fresh fruits and vegetables which carried injurious residues of poisonous chemical sprays were made, and 32 prosecutions of shippers of such commodities were instituted. The commodities seized included cauliflower, celery, lettuce, cabbage, pears, apples, and crab apples.

During the shipping season, members of the Food and Drug Administration spent literally night and day taking samples from the enormous traffic in fresh fruits and vegetables moving from producing points to marketing centers. Products other than fresh fruits and vegetables also were found to contain potentially injurious residues of arsenic or lead. Among these products were vinegar and apple pomace, chops, and pulp. The Government seized and destroyed 72,000 gallons, or one tank car, of vinegar which was adulterated with arsenic. In the survey of products made from fruits sprayed with lead arsenate, the Administration caused the seizure, in 1 month, April, of approximately 5,500 bags of adulterated apple pomace. The food was shipped by producers in towns in Pennsylvania, New York, Missouri, Michigan, and Washington to consignees in various parts of the country. The pomace was found to contain residues of arsenic or lead, both poisonous.

Spray-Residue Removal

It is necessary for growers to use chemical sprays in order to control the ravages of insect pests. Lead arsenate, calcium arsenate, and other chemical combinations have been found to be effective in destroying insects which prey upon crops. The grower, in order to obtain a crop at all, must use sprays, some of which are potentially injurious to the health of consumers. But the Department's duty to the public in the enforcement of the pure food and drug law necessitates rigid checking of all shipments of fresh fruits and vegetables which contain such residues of chemical sprays as may be harmful to the consumer. Proper cultural practices, in the production of fruits and vegetables, combined with careful washing of the commodity before marketing, are effective in removing spray residue.

In regulatory control over interstate and foreign shipments of adulterated or misbranded foods, drugs, and stock feeds, the Depart-

ment seized 1,195 consignments of foods, 416 shipments of drugs, and 13 stocks of stock feeds. The year's prosecutions of manufacturers or shippers totaled 638 for foods, 453 for drug products (including livestock remedies), and 62 for stock feeds. Drug seizures included 74 consignments of livestock remedies which were adulterated, misbranded, or both, and 16 prosecutions were instituted in the case of livestock-remedy shipments. The year's grand total of all prosecutions and seizures of foods, drugs, and stock feeds was 2,777.

Seizures covered a wide variety of adulterated or misbranded foods, including short-weight butter, partially decomposed fish and sea foods, fresh fruits and vegetables which carried residues of poisonous chemical sprays, and many other products. The Government also removed from the market, by seizure, a large variety of patent or proprietary remedies, falsely and fraudulently labeled as being effective in the cure of such serious diseases as tuberculosis, pneumonia, diabetes, venereal disease, Bright's disease, cancer, and other maladies.

FEDERAL-AID ROAD CONSTRUCTION

Projects involving the improvement of 13,255 miles of the Federal-aid highway system were completed during the fiscal year with Federal assistance. On 8,503 miles the work consisted of initial improvements, so-called because it was the first to be carried out with Federal aid on this particular mileage. On 4,700 miles previously improved with Federal aid to some extent, the years' work raised the condition of the roads to a higher level of improvement and was classed as stage construction. On the remaining 52 miles the work completed was classed as reconstruction.

The total cost of the projects completed during the fiscal year 1933 was \$234,383,376, of which \$104,673,506 was paid outright as aid by the Federal Government and \$4,502,467 was advanced from the emergency appropriation of \$120,000,000 made by the Emergency Relief and Construction Act of July 21, 1932. Many of the projects completed during the fiscal year were begun in previous years; the above expenditures were not confined to the single year but were made throughout the period of construction.

Actual disbursements of Federal funds during the year, including all sums paid for work in progress, amounted to \$101,266,331 of regular Federal-aid funds, and \$62,131,961 of emergency construction funds.

The mileage completed during the year brings the total classed as completed to 107,869 miles, which excludes 3,986 miles in course of stage construction or reconstruction at the end of the fiscal year.

The total completed mileage includes more than 543 miles of bridges more than 20 feet in span and their immediate approaches, 47,329 miles surfaced with high-type pavements, 8,800 miles with 47,329 miles surfaced with high-type pavements, 8,800 miles with intermediate-type surfaces, 39,420 miles with low-type surfaces, and 11,777 miles unsurfaced but graded and drained to satisfactory standard.

At the close of the fiscal year work was in progress on 12,383 miles of the Federal-aid system. This included, in addition to the 3,986 miles of stage construction above mentioned, 8,397 miles on which no previous Federal-aid work had been done.

Emergency Funds

The Emergency Relief and Construction Act of 1932, approved July 21, 1932, appropriated \$120,000,000 to be advanced to the States for use in lieu of State funds to match the regular Federal-aid funds available. The sums advanced are to be reimbursed to the Federal Government by deduction from future Federal-aid appropriations over a period of 10 years commencing with the fiscal year 1938.

It was originally provided that only such parts of the sums apportioned as were actually expended for work performed before July 1, 1933, should be available. By subsequent amendment of the act the period of availability was extended to December 30, 1933.

On June 30, 1933, the original terminal date, all but \$3,258,018 of the \$120,000,000 appropriated had been obligated to definite construction projects and \$85,254,000 had been earned by the completion of work. Of this amount \$62,131,961 had been actually paid to the States.

The effect of this expenditure upon the volume of employment afforded by road work appears in the differences between employment figures for the fiscal years 1932 and 1933. In the former year only regular Federal funds were available for expenditure during the 10 months from September 1931 to June 1932, inclusive. During the first 2 months of the year the emergency appropriation of December 1930 was still being spent. Last year these conditions were reversed. Only regular Federal-aid funds were expended in July and August, and the expenditure of the \$120,000,000 emergency appropriation began in September and continued throughout the year.

During the 10-month period of the fiscal year 1932, when only regular Federal-aid funds were available, the total direct employment afforded by Federal-aid road work was 524,170 man-months. During the similar period of the fiscal year 1933, work provided by the \$120,000,000 emergency appropriation swelled the total of employment afforded to 1,085,144 man-months, or more than double the previous year's total.

On all Federal and State road work, including Federal work in the national forests and parks and public lands and independent State construction and maintenance work, direct employment totaled 2,666,058 man-months in the 10 months of the fiscal year 1932. The same classes of work in the 1933 period produced direct employment in the amount of 3,200,320 man-months, a gain in the latter year of 534,262 man-months. This gain was attributable entirely to the expanded Federal contribution.

Expenditure of the emergency funds beginning in September 1932 caused a sharp rise in employment on Federal-aid work from an average of 84,675 men in August to an average of 117,975 in September. Continuing at 117,024 in October the number employed rose to a peak of 123,389 in November and then dropped to a low of 72,592 in January 1933, after which it again rose quickly month by month to a midseason peak of 142,957 in June 1933. At midwinter the Federal-aid work of the last fiscal year gave employment to nearly 50,000 more men than were employed during the preceding winter. At midsummer the past year's employment exceeded that of the previous year by more than 70,000 men.

National Forest Roads and Trails

Construction of 359 miles of forest highways was completed during the fiscal year 1933. At the close of the year there were 5,593 miles of improved roads in the forest highway system.

Forest highways are the main roads traversing the forest areas and connecting with the Federal-aid highway system at the reservation boundaries.

WEATHER BUREAU

It was necessary to maintain the regular activities of the Weather Bureau at an expenditure from 20 to 25 percent less than that of recent years.

Various services had to be curtailed. Means were adopted, however, which increased the effectiveness of reports received from ships at sea, especially during the prevalence of hurricane conditions in the waters of the Caribbean Sea and the Gulf of Mexico. This was done with the cooperation of the major radio companies, whose stations along the South Atlantic coast make special calls for reports at designated hours from ships known to be in the areas in which a tropical disturbance is in progress.

The so-called "International Polar Year" extended from August 1, 1932, to August 31, 1933. By elaborate and concerted agreements between all meteorological services of the different nations, including intimately related scientific organizations, the year was marked by a unique set of complete and intensive observations of meteorological and related natural phenomena, especially at stations in high polar latitudes in the Northern Hemisphere. This work commemorated a somewhat similar project inaugurated in 1883. Analysis and development of the results obtained by this unique system of international observations will be extremely valuable.

HENRY A. WALLACE,
Secretary of Agriculture.

WHAT'S NEW IN AGRICULTURE

AGRICULTURAL Adjustment Measured in Progress Toward Parity Prices

It is the purpose of the Agricultural Adjustment Act to raise the purchasing power of farm commodities to the pre-war par-

ity. Progress toward that goal, however, cannot be rapid, for agriculture has tremendous maladjustments to correct, and recovery depends also on factors influencing demand. Nor can we look for uninterrupted progress. Setbacks are inevitable. Still less can we expect an unbroken advance, a gain embracing all farm products equally and simultaneously. Each product has problems peculiar to itself as well as problems common to the entire list of agricultural commodities. Some commodities have to stand the full force of world competition; others have to meet only domestic competition. The acreage of some crops can be readjusted quickly; whereas the acreage of others, as for example orchard crops, tends to remain relatively constant for long periods. Certain crops, such as cotton, can be cut down without stimulating directly competing farm production. It is different with beef cattle or hogs.

Agricultural recovery involves adjustments internal as well as external. It necessitates shifts in the relationship of one crop to another in addition to a reduction in the total farm output. The job requires not merely a few big moves but many small ones. It calls for tactics as well as strategy, and its various stages will show up in constantly shifting price relationships. So that farmers may know how the battle is going and may see what its shifting positions oblige them to do, they should have maps; that is to say, price charts indicating for farm commodities as a group, and for important products separately, how actual price trends compare with parity prices. This article includes a number of such charts with explanatory text. It records some of the results attained in 1933 and in the early months of 1934.

Agricultural Adjustments Required by Law

Under the Agricultural Adjustment Act, Congress required the United States Department of Agriculture to do certain things calculated to increase the purchasing power of farm commodities. Specifically, it directed the Department to get the cooperation of farmers in crop adjustments and to enter into marketing agreements with producers, processors, and distributors of agricultural products with the object of eliminating certain competitive wastes, improving trade practices, moving surpluses into consumption, and raising farm-commodity prices. This agricultural-recovery legislation was part of a comprehensive measure which provided also for farm-mortgage relief and for the raising of prices through monetary action. In its application to agriculture the measure contemplated substituting planning for blind competition as the controlling factor in prices.

In ordinary circumstances it is not incorrect to say that the cure for low prices is low prices. This idea is one expression of the old *laissez-faire* doctrine, which assumes that low prices eventually correct themselves by curtailing production. Normally, low prices do cause needed readjustments in production, particularly if the price difficulty involves only a few commodities. Farmers then turn to other products until shortages improve the market for the depressed commodities. Low prices have not this self-correcting property when the declines are universal and excessive. General price depressions, on the contrary, may actually stimulate farm production by forcing individual producers to offset by volume what they lose on unit prices. Low prices then tend to be self-perpetuating rather than self-correcting.

Prices, moreover, do not depend exclusively on the relation between production and consumption. They respond greatly to monetary influences and to the expansion or contraction of credit. Maladjustments in production explain only part of the price declines that occurred from 1929 to 1933. Farm commodities in March 1933 had only half their pre-war purchasing power because world finance as well as world production was disordered. It would have been wholly unpractical to expect a complete remedy from production adjustments alone. Congress provided accordingly for monetary and credit action as well. It set up a definite goal of price improvement and launched a series of complementary recovery policies. In the short period that has elapsed since the enactment of recovery legislation prices have risen substantially; nevertheless, the goal is still distant. This article indicates what has been accomplished and what still remains to be done.

Division of Responsibility

The United States Department of Agriculture administers only one part of the agricultural-recovery legislation. Mortgage relief is the task of the Federal Farm Credit Administration and monetary policy is the President's responsibility. Obviously, the price gains recorded herein cannot be attributed exclusively to the crop-adjustment programs and marketing agreements sponsored by this Department. They reflect also improvement in consumer buying power, and in the case of international commodities such as wheat, cotton, and wool, they reflect the influence of our new monetary policy. It will be long before the specific influence of the separate recovery factors can be measured separately. Undoubtedly, however, the production adjust-

ments promoted by the Department will have a powerful influence. Moreover, production is a controllable factor in which each farmer has a keen individual interest. The charts and accompanying text, therefore, emphasize the production aspects of the price-recovery problem, without suggesting that these are the only factors.

In title I of the agricultural legislation, Congress declared it is necessary "to establish such a balance between the production and the consumption of agricultural commodities as will restore the purchasing power of farm products to the level of the base period." It adopted as the base period the pre-war years, August 1909 to July 1914, for all the commodities named in the act except tobacco. For tobacco, Congress fixed the post-war period, August 1919 to July 1929, as the base period. In this declaration the act defined the goal. The charts here given show the difference between current prices of various commodities and the prices that would be necessary to give farm products the desired purchasing power.

The Basis of Parity

The basic commodities for which the Agricultural Adjustment Act (of May 1933) seeks to establish the pre-war level of purchasing power are wheat, cotton, corn, hogs, rice, milk, and milk products. It aims generally, except in the case of tobacco, at the same goal for other farm products.

In taking the pre-war years as the basis for reckoning parity, those who sponsored the act undoubtedly had in mind the fact that the situation then, besides being reasonably favorable to agriculture, had signs of stability. It was the result of a long evolution, in which the important price-making forces had struck a balance. The post-war trend of prices, in which farm products lost purchasing power heavily, clearly betokened maladjustment. It was logical to aim at restoring the price relationships that had prevailed when conditions were satisfactory. Congress chose a post-war base for tobacco because recent changes in the demand for different types of that commodity, and also in tobacco production, made pre-war parity unsuitable as a purchasing-power yardstick.

In the several charts given herewith, the curve representing parity prices is identical, by definition, with the curve representing the prices of the commodities that farmers buy in exchange for their farm products. Before the war a given quantity of farm products would exchange for a given quantity of other goods. The Agricultural Adjustment Act aims to make the same exchange possible again. Curiously, in the early months of 1933, or just prior to the enactment of the law, the prices of the things that farmers buy had dropped to about what they had been before the war. Prices of the things that farmers sell, however, were about 50 percent lower. In other words, a 100-percent increase in the prices of farm goods, assuming no change in the prices of nonfarm goods, would have been necessary at that time to restore the pre-war parity for farm commodities as a group.

Certain farm commodities last spring were below the general average. Wheat, for example, had an average farm price in March of only 34.5 cents a bushel, as compared with a pre-war average of 88.4 cents. An increase to the latter figure, with no change in the prices of the things farmers buy, would have restored wheat to parity. Wheat rose during the summer; but so did prices generally. In consequence, a dis-

parity persisted between the prices of wheat and the prices of nonagricultural goods, though the spread was somewhat reduced. Other commodities responded, as the charts show, in different ways to the general situation, but most of them had still far to go toward parity as the year ended. Full recovery according to the standard set by the act would bring the curves of actual prices plus benefit payments and the curves of parity prices together. In other words it would remove the disparity between agricultural and nonagricultural prices. That is the ideal. But the curve of prices received by farmers can never synchronize exactly with the curve of prices paid by them. Approximate synchronization is the practical goal.

Agricultural and Nonagricultural Prices

It is impossible to understand the present position of agricultural prices without viewing it against the background of long-time price movements. Since 1800 commodity prices generally, both agricul-

FIGURE 1.—Wholesale-price index numbers of all commodities and of farm products, United States, 1798-1933.

tural and nonagricultural, have been in three profound depressions. One such depression followed the Napoleonic wars, another followed the American Civil War, and the third followed the World War of 1914-18. In each case the depression succeeded tremendous inflation associated with war activities. Figure 1 shows these depressions and also the vitally important relationship of agricultural to nonagricultural prices. In the nineteenth century and during the first decade and a half of the twentieth century, agricultural prices tended generally upward and nonagricultural prices generally downward. This gave agricultural commodities a steadily increasing exchange value or purchasing power. It reflected mainly the fact that we had surpluses of farm commodities and shortages of industrial goods. We exported the former largely and imported the latter. Increasing industrial productivity, a result of science, invention, improved transportation, and the development of mineral resources, brought relatively lower industrial prices. In the World War period, from 1914 to 1919, farm and nonfarm prices rose together, with farm prices slightly higher at the peak. In the two post-war depressions, agricultural prices dropped much more than other prices. This reversed the former uptrend in agricultural purchasing power.

Post-War Price Disparity

There has been a disparity between agricultural and nonagricultural prices since 1920. The disparity has become much wider since 1929. In the economic recovery that followed the first post-war depression of 1920 and 1921, the disparity narrowed. Farm commodities rose in purchasing power during this period because industrial conditions stimulated the demand both at home and abroad, because this country had short grain crops in 1924 and 1925, and because heavy industrial production kept industrial prices from rising. After 1925 agricultural prices ceased to improve in relation to other prices. Among the causes of the change were a decline in the foreign demand for American farm products, an increase in foreign agricultural production, and continued heavy farm production in the United States. Farm purchasing power could not make headway against the combined influence of a restricted foreign demand and an unrestricted United States production. After 1929 nonagricultural prices declined also; but far less sharply than agricultural prices. Hence, the unfavorable disparity between farm

FIGURE 2.—Index of prices received and paid by farmers.

and factory goods increased. At the beginning of 1933 farm commodities had only half their pre-war purchasing power. These remarks apply, of course, to the average of farm commodity prices, which express the net trend of many different products, each reacting differently to the price-making influences. Conditions bearing particularly on the different commodities are illustrated in the charts and explanations that follow.

Consumers' Purchasing Power

Overlong periods, prices largely reflect monetary changes. In shorter periods, the purchasing power of consumers is a dominant influence. Consumer buying power naturally declines during depressions, and the demand for commodities falls. In the United States the money income of consumers other than farmers dropped about 50 percent from the middle of 1929 to the spring of 1932. Earnings of industrial workers such as factory and railroad employees and men engaged in mining and construction fell nearly 70 percent. Unemployment was the chief cause of the decline; reduced wage rates contributed. This change in consumer buying power affected agricultural prices more than non-

agricultural prices because stocks of farm commodities accumulated while stocks of nonagricultural goods, generally speaking, did not. Farms continued to produce, whereas factories closed down. Depressions cause a surplus of goods in agriculture and a surplus of labor in industry. It takes longer to readjust farm production than factory production, and a price disparity against agriculture is a natural consequence.

FIGURE 3.—Income of industrial workers and urban consumers, 1919-33.

Post-War Boom and Collapse

In sharp contrast with the relatively stable course of agricultural income in the United States from 1924 to 1929 was the speculative and industrial boom. This boom, however, was not marked by sharply rising commodity prices. On the contrary, the price level, after a decline in 1920, remained relatively stable until 1929. Industries expanded their production, and the increased output at stable prices brought increased profits and supported tremendous speculation in securities. The boom derived impetus from an inflow of gold and from domestic credit expansion at declining rates of interest. As is well known, it came to an end in 1929. Among the factors prominent in the collapse were: Uncoordinated and unbalanced expansion in certain branches of industry; extreme maldistribution of the national income between city and country areas; a much greater percentage increase in profits than in wage payments; increased competition in foreign markets, especially in agricultural products; the efforts of many countries to put their currencies back on the gold standard; and in 1929 a sharp decline in loans by the United States to foreign countries. Improvement during the summer of 1933 followed the enactment of the Agricultural Adjustment Act and the Industrial Recovery Act, and the inauguration of a new monetary policy. A recession during the second half of the year promised to be only temporary. There were evidences of continued revival, with indications that agriculture would share it.

FIGURE 4.—Indexes of prices of industrial stocks and commodities, interest rates, and industrial production.

Interdependence of Farms and Factories

Farm incomes stand in a close relationship to factory pay rolls in the United States. This is evident, from figure 5, for quite short periods as well as over relatively long terms. During 1933, for example, the cash incomes of dairymen and poultrymen rose with factory pay rolls, after having fallen with factory pay rolls in 1931 and 1932. In commodities such as cotton and grains that depend more on international price conditions the correlation is less close. Farm commodities taken as a group vary quite closely with factory pay rolls. Practically everything produced on the farm enters the industrial world as raw material for food and clothing industries, as material for transport by railroad or steamship, or as the basis for various services. Industries using agricultural raw materials handle more than 41 percent of the materials consumed in manufacturing in this country. The interde-

pendence of farms and factories is permanent and practically unvarying. Farm recovery requires as a principal element an increase in the buying power of consumers.

FIGURE 5. - Factory pay rolls and cash income from farm products (adjusted for seasonal variation, 1924=100).

Speculative Commodities

Basic commodities that move in world trade have responded more strongly to the administration's monetary policy since April 1933 than have commodities sold mainly in the domestic market. In May, June, and early July, expectations of inflation caused a flight from the dollar, accompanied by great speculation in commodities. In the domestic

FIGURE 6. —Prices of six speculative commodities in the United States and the price of gold in dollars and in sterling April 1933 to March 1934. Index of near-futures prices of wheat, cotton, cottonseed oil, and sugar, and cash price of copper. The price of gold here used is the open-market price in London. The lower line shows changes in gold value of the pound sterling since suspension of gold payments in the United States.

markets the demand for these speculative commodities exceeded the demand for currency. In the foreign markets the depreciation of American currency gave it an added purchasing power for American products. In consequence largely of the initial speculative activity, the United States currency prices of the commodities covered in the chart rose far above their gold equivalents of April 1933. Subsequently, these prices declined below their gold equivalents. The gold-purchase policy adopted by the Government in October preceded a cut of 40 percent in the quantity of gold in the dollar. It will undoubtedly have more effect for some time on grain and cotton and other commodities largely exported than on livestock and dairy prices, which depend primarily on domestic purchasing power. Eventually, however, most of our raw-material prices should share directly or indirectly the effect of reducing the quantity of gold in the dollar. It is well to bear in mind the probability that the favorable influence of our monetary policy on the prices of cotton and wheat and other international commodities may not continue if foreign countries reduce the weight of gold behind their currencies as we do.

Cotton

Cotton prices in the United States declined from about 78 percent below the parity level in the fall of 1930 to about 38 percent below that level in the summer of 1932. Then came a temporary, partial recovery followed by another decline to about 45 percent below the parity level in the early part of 1933. There was a marked recovery up to July 1933, then a reaction until September, when the market turned hesitantly upward again. In September the Commodity Credit Corporation was organized to loan farmers 10 cents per pound on unmarketed cotton for participation in the 1934 acreage-reduction campaign.

Outstanding among the causes of cotton's terrific slump in 1931 and 1932 was a huge cotton surplus that arose out of the world-wide curtailment in consumption and the large 1931 crop. At the beginning of the 1932-33 season the world carry-over of American cotton was about 13,000,000 bales—approximately two and a half times the normal carry-over. By the beginning of the 1933-34 season the world carry-over of American cotton had been reduced to about 11,600,000 bales, and because of the removal of 10,400,000 acres from the 1933 harvest the supply for the 1933-34 season was 24,700,000 bales. While this supply was 1,300,000 bales less than that of the previous season it was the third largest in history. Without the adjustment program, the year's crop would probably have been the second largest thus far produced and the supply about 3,000,000 bales larger than that of any other year in history.

With the 1933-34 supplies of foreign cotton larger, the world supply of all cotton is the largest in history despite the smaller supplies of

FIGURE 7.—Farm and parity prices of cotton, and benefit payments.

American. Had this country not cut down its acreage the world supply of all cotton would have been by far the largest on record. Hence, the price recovery that took place in 1933 resulted only to a very moderate degree from an improved supply situation. Mainly it reflected the Federal Government's monetary policy, the speculation connected therewith, and the general economic improvement which occurred. Lasting recovery in cotton prices awaits substantial crop adjustments. The rental benefit payments on the 1933 crop together with the value of options, amounted to about 4 cents per pound on the production of those who participated. This amount added to the current farm price came close to giving the participating cotton farmers pre-war parity on the domestically consumed portion of the crop.

Cottonseed

Cottonseed prices declined sharply and almost continuously from 1927-28 to 1931-32. They recovered, and again declined, in 1933, in sympathy with cotton prices and general economic and monetary developments. Cottonseed prices usually tend to vary with cotton prices

because the supplies of the two commodities naturally go together. There are, however, important differences in demand and variations in the supply of competing commodities. Consequently, prices of cotton and cottonseed do not always move together.

Prices obtainable for cottonseed oil, and for other cottonseed products, depend materially on the supply of competing commodities, such as lard and various vegetable oils. Large supplies of cottonseed accumulated in the crushing mills in 1931-32, and 1932-33, and stocks of cottonseed oil increased markedly. Stocks of other vegetable oils were large, and in the first half of 1932 stocks of lard began accumulating. In consequence, the average price of prime summer yellow cottonseed oil in New York in May 1932 was only 46 percent of the pre-war average.

In the spring and summer of 1933 a strong speculative demand for cottonseed, cottonseed oil, and competing commodities produced a

FIGURE 8.—Farm and parity prices of cottonseed.

sharp advance in the cottonseed and cottonseed-oil markets, but a renewed decline in the fall carried them back about to the average of 1932-33. Stocks of cottonseed at mills at the beginning of the 1933-34 season, though 26 percent smaller than a year earlier, were still five times as large as the average of the previous 5 years. On September 1, 1933, storage stocks of lard, the chief competitor of cottonseed oil, were at a record level.

The trend in consumer incomes and demand, as well as the supply of cottonseed, cottonseed products, and competing commodities, will greatly affect the effort to restore cottonseed prices to parity. The planned heavy reduction in cotton acreage in 1934 and the Federal emergency hog-production-control plan should strengthen the situation materially.

Wheat

In 1931 the farm price of wheat fell to 35 cents per bushel or to less than 30 percent of the parity price. The cause, in the most general sense, was of course the depression, with the decline in prices in general, and the curtailment in international trade, which reduced the purchasing power of consumers everywhere and caused wheat stocks

to pile up. But wheat prices reflected certain special conditions also. Wheat production throughout the world shifted greatly during the war. After the war the countries which had increased acreage were not inclined to return to the pre-war level, while the European countries whose production had fallen off during the war made strenuous efforts to increase it. Exporting countries with large supplies encountered severe restrictions on the importation and use of wheat by European countries.

The low price of wheat, which might have been expected to make for a reduced world wheat acreage, did not have that effect immediately. World wheat acreage outside Russia and China reached the peak level in 1932-33, and has not since declined significantly. Acreage has declined somewhat during the last 4 years in the exporting countries, but has risen in the importing countries. World wheat acreage

FIGURE 9.—Farm and parity prices of wheat, and benefit payments.

reached a peak at 263,900,000 acres in 1932-33, and dropped only to 263,300,000 in 1933-34.

The world wheat market continues to be depressed by accumulated stocks, a high level of production, and restrictions on international trade. Nevertheless, wheat prices in the United States are nearer to parity than the existing supply-and-demand situation would normally permit. They rose above export basis in 1933 because the United States crop was extremely small, because the Federal Government launched an acreage-reduction program and aided exporting in the Pacific Northwest, and because the American dollar depreciated in terms of foreign exchange. Benefit payments of 28 cents per bushel, the first installment of which was made in November-December, gave participating farmers practically parity prices on the domestically consumed portion of the crop.

Corn

From a level of about 90 cents per bushel in the autumn of 1930, when the crop was very short, the average farm price of corn fell rapidly to 19 cents in December 1932. In September 1930, when selling at 92 cents per bushel, it was just about equal to parity, while in Decem-

ber 1932 corn was selling for only 28 percent of the parity price. Prices were so low in 1932 that in many areas corn sold in the cash markets hardly paid the cost of marketing. Fed to livestock, however, it generally gave a better return.

Following March 1933, corn prices rose very rapidly, reaching a peak in July. In some localities the July level of prices was 300 to 400 percent higher than the low point. The sharp rise, however, stimulated heavy selling of corn in the cash markets, and market supplies reached record levels. As a result partly of the increased market supplies and partly because of a speculative reaction from the very rapid advance, prices declined, and in October they were about 30 percent below the July peak.

In considering the returns to corn growers, the prices of livestock must always be taken into account because most corn growers feed their grain to livestock instead of selling it. Another important consideration is the opportunity corn producers in a number of States have of securing loans from the Commodity Credit Corporation of 45 cents

FIGURE 10.—Farm and parity prices of corn.

per bushel at country points. The Agricultural Adjustment Administration is helping increase returns to corn growers through both corn-acreage reduction and reductions in hog numbers. It is to be expected that while livestock prices had not been improved by the end of 1933, they will eventually be benefited both because of the direct effect of reducing hog numbers and because the relatively higher corn prices will tend to reduce livestock production.

Hay

The July, August, and September 1933 prices for the hay crop averaged about 12 percent higher than the prices paid in the same period of 1932. Meantime, feed-grain prices were approximately 54 percent higher. The 1933 hay crop, though a short crop, was not reduced relatively as much as the feed grains. The production of both tame hay and wild hay was 9.2 percent below the 1926-30 average. With the carry-over on farms May 1, however, the hay crop exceeded the annual disappearance of hay during the last 4 years, and seemed sufficient to

meet the requirements of a slightly increased number of hay-consuming livestock. In most of the Cotton Belt, which until recent years purchased a large proportion of its hay from distant points, the supplies were ample for local needs.

Regulations under the Agricultural Adjustment Act for reducing the acreage in cotton, wheat, corn, and tobacco permit farmers to grow erosion-preventing and soil-improving crops. It is not yet possible

FIGURE 11.—Farm and parity prices of hay.

to estimate how this policy will affect the hay and pasture situation. It seems likely to result in an increased acreage of both hay and pasture, particularly the latter. Probably hay will not advance in price relatively as much as will certain other crops. This does not necessarily mean that hay and pasture will be unprofitable. Land in pasture produces usually less than half as much total feed per acre as land seeded to cultivated crops. But the lower production may result in greater returns per acre because pasture requires less labor.

Oats

Our production of oats in 1933 was less than 60 percent of the 1926-30 average production, and was the smallest crop since 1894. This decline, together with monetary and other developments, caused oat prices to climb sharply. In July 1933 they came near to the parity level but declined thereafter to about 40 percent below that level. The resulting net gain, however, was a considerable improvement over the situation that prevailed during 1931 and 1932.

In February 1933 oats had a little less than 33 percent of their pre-war buying power. This was a result mainly of the depression but also of a declining need for oats as a feed for work animals. Mechanization in agriculture and the replacement of horses by engine power in city transport tremendously restricted the market outlet for oats, which, nevertheless, retained an important place in agricultural rotations.

The oat price gain of 1933, a result partly of short-feed conditions and partly of recovery forces set in motion by the National Government, does not necessarily indicate a prospect of permanent recovery. Normal weather conditions and an acreage of oats equal to that of recent years would undoubtedly bring lower prices again. Commercial

utilization of oats is not an important factor. The resumption of brewing and distilling will not greatly increase the total consumption of oats.

FIGURE 12.—Farm and parity prices of oats.

The total supply of feed grains for the 1933-34 season is smaller than that for any other year since 1901. Oat prices will, of course, benefit from the Government's program for reducing the production of corn.

Flaxseed

Flaxseed prices rose temporarily above the parity level in July 1933 and have since then retained most of that gain. The sharp advance from about 50 percent of parity at the end of 1932 to near parity levels was due largely to monetary changes and prospects of reduced domes-

FIGURE 13.—Farm and parity prices of flaxseed.

tic supplies. From 1929 to the spring of 1933, however, the spread between the actual and the parity price of flaxseed ranged from 50 to 60 cents a bushel.

Domestic flaxseed supplies for the 1933-34 season are much below the expected requirements, as a result of record low yields and a reduced acreage. On the other hand, the market demand for flaxseed

and flaxseed products seems likely to be somewhat improved. The acreage sown to flaxseed in the United States has declined sharply during the last 3 years, and in 1933 was the smallest since 1922.

It may be necessary to import as much as 13,000,000 bushels of flaxseed to supplement the domestic supply. The United States production in 1933 was the smallest since 1919. World production also was smaller. These circumstances make it probable that flaxseed acreage in the United States will be substantially increased in 1934.

An acreage 50 percent larger than the 1,925,000 acres seeded in 1933, with an average yield per acre, would produce about as much flaxseed as could be disposed of without losing the benefit of the 65-cent-per-bushel tariff. It is not likely that the 1934 crop will exceed domestic requirements.

Hogs

After declining almost steadily since 1930, hog prices reached the lowest level in more than 50 years late in December 1932. This drastic decline was the result of the sharp reduction in consumer incomes and

FIGURE 14.—Farm and parity prices of hogs.

the marked curtailment of the export outlet for United States hog products. Exports increased greatly during the World War, and were at a relatively high level in the years immediately following the war. During the last decade European countries restored their hog production, and our export outlet was greatly curtailed. Hog slaughter in the United States is now considerably larger than during the war period, when exports were at their peak. The world-wide depression during the last 4 years greatly reduced the demand for hog products both at home and abroad, and the hog industry is now faced with an obstinate surplus problem.

Hog prices advanced somewhat during the first half of 1933, but since July prices have declined to some extent. The advance was largely a reflection of some improvement in the domestic demand for hog products. Federally inspected slaughter of hogs in the marketing year ended September 30, 1933, was larger than in any other year since 1928-29. The export outlet continued to be sharply restricted. Total exports of hog products in 1932-33, though slightly larger than in the previous year, were about 5 percent smaller than in 1930-31 and much below

those of the years from 1920 to 1929. Hog production in Europe has declined during the last 2 years, but restrictions to international trade have prevented this decline from strengthening the foreign outlet for American hog products. A number of factors contributed to the decline in prices between September and December 1933. Ordinarily marketings expand during this period and bring about a seasonal price decline. This year marketings were unusually heavy, induced in part by the relatively higher prices obtainable for corn. Consumer incomes failed to advance after October. The processing tax on hogs of 50 cents a hundred pounds in November and \$1 in December in the face of heavy marketings and a temporary check to business activity also contributed temporarily toward lower prices. On February 1 the tax was increased from \$1 to \$1.50 a hundred pounds. Hog receipts were falling off about that time and purchases for relief distribution were being increased. Prices of hogs advanced during the last half of January and the first week of February 1934.

Commercial slaughter of hogs during the 1933-34 marketing year, which began October 1, 1933, will be considerably smaller than that in the preceding marketing year. This expected reduction will take place largely as a result of noncommercial slaughter of some 6,000,000 pigs in the late summer of 1933 under the Federal emergency hog-production-control plan. Recently the Agricultural Adjustment Administration announced a more permanent plan for hog-production control. This plan provides for a reduction in the number of pigs raised by cooperating farmers of 25 percent from the average production in 1932 and 1933. Such farmers will also agree to reduce their corn acreage by 20 percent. Some reduction in pigs raised during 1934 probably would have occurred in any event, but the reduction contemplated under the production-control program is of much greater proportions.

Widespread cooperation by hog raisers in the Administration's hog-production-control plan will be necessary to raise hog prices to parity. The fair-exchange value or parity price of hogs in October 1933 was more than twice as high as the prices then received. In each of the last 2 marketing years the inspected commercial slaughter of hogs has been about 47,000,000 head. General participation by producers in the hog-control program would reduce this total during 1934-35 to a point lower, it is believed, than that of any other marketing year since 1920-21, when the slaughter was 38,663,000 head. Such a reduction, coupled with improved demand produced by general economic recovery, would probably raise hog prices substantially toward parity. These higher prices with adjustment payments added would give the hog farmers more purchasing power than they have had for several years.

Wholesale Price of Milk

Gross returns from dairying since 1929 have been relatively favorable as compared with returns from most other types of farming. The comparative situation may be less favorable during the next year or two if supplies are maintained in the face of low demand and relatively high feed costs. The number of milk cows on farms has increased continuously, except for seasonal fluctuations, since 1929. Milk production has not increased proportionately, but excess production capacity exists; and, with more liberal feeding, milk production could be increased materially. Stocks of dairy products were at record levels in the fall of 1933, and consumption had declined.

Farm prices of milk at wholesale began to decline in the fall of 1929 and continued to decline until the spring of 1933. True, the down trend started later than the slump in other farm commodities, and was less marked. In 1933 price-supporting measures taken by the Agricultural Adjustment Administration strengthened the dairy-price situation. The basic supply-and-demand position, however, is not favorable. In recovery periods following previous depressions, dairy prices have lagged somewhat. This seems likely to be the case again. Any further considerable rise in milk prices will probably require a distinct rise in the general price level and in consumer buying power, or a noticeable reduction in supplies.

Farm prices of milk at wholesale, as shown in the chart, cover not only milk sold for distribution as fluid milk and ice cream, but milk for condensing, drying, and cheese-making. Some of this milk, indeed, goes into the production of butter, though cream sold from the farm furnishes most of the fat used in buttermaking. Milk for the fluid

FIGURE 15.—Wholesale and parity prices of milk.

market usually brings higher prices than milk for processed dairy products. Hence, the price trend shown above records a greater spread between the actual and the parity price than would be indicated by a chart covering fluid milk exclusively. The upswing in 1933 reflects the influence of the Government's monetary policy and the resulting increase in business activity and consumer buying power. It shows the effect also of various things done by the Agricultural Adjustment Administration, including the adoption of milk agreements and the removal of quantities of butter from the commercial market.

Retail Price of Milk

Farmers themselves retail annually probably 10,000,000,000 pounds of milk. This is about one seventh of the milk or milk equivalent produced in the United States. The price trend for the fluid milk thus retailed shows a less drastic decline since 1929 than the retail prices of other dairy products, and a less severe decline also than that shown by the price of milk sold by farmers at wholesale. This difference results mainly from two facts: (1) The normal tendency of fluid milk for which the demand is relatively constant, to hold up relatively better than

other dairy products during depressions; and (2) the well-known tendency for retail prices to decline less than wholesale prices in the early stages of depressions, because they contain a larger proportion of relatively high distribution costs that do not decline readily.

These circumstances strengthened the farmers' incentive to retail their milk direct. Such retailing has increased substantially in the last few years. It has important consequences. Increased retail selling by independent farmers makes it more difficult for the organized producers to maintain their prices and may eventually oblige distributors to take smaller margins. So far during the present depression, milk retailed from the farm has maintained a more favorable relation to the parity price than other dairy prices. In the recovery of 1933 the spread between the actual and the parity price was slightly narrowed. Whether this favorable position can endure depends, to a considerable extent, on the volume of milk retailed by farmers and on the reaction of organized producers to this competition.

In this connection the distinction between fluid milk retailed by farmers and milk sold by farmers at wholesale is fundamental. The

FIGURE 16.—Retail and parity prices of milk.

retailed milk is all for the fluid market. That sold at wholesale is partly for fluid uses and partly for processing into butter and other manufactured products. It does not necessarily follow, because the retail-price curve looks relatively favorable, that the independent farm retailers have been getting a more advantageous price for their class 1 milk than the sellers at wholesale. The farmer-retailers have to include their costs of distribution.

Butter

Up to the winter of 1932-33 returns from butter were relatively favorable. Butter prices slumped severely in the spring of 1933. Even then, the spread between the actual and the parity price was smaller than in the case of many other major farm products. Production continued to increase, however, and a speculative movement provoked a reaction. The result was an unseasonal decline in prices and a widening of the spread between the actual and the parity price.

The Department of Agriculture removed a considerable quantity of butter from the market and arranged for its distribution to the unemployed through the Surplus Relief Corporation. This action merely steadied the market, without materially changing the supply-and-

demand situation. Full recovery in butter prices depends essentially on a revival of city buying power.

Cold-storage holdings of creamery butter in December 1933 totaled 138,090,000 pounds—more than 68,000,000 pounds above the average for that month. They included the Government purchases. From March to September the farm price of butterfat increased 29 percent. In the same period, however, the parity price of butter increased through advances in the prices of nonagricultural commodities. In December the farm price of butter averaged 21.7 cents a pound and the parity price 30.2 cents. The disparity was practically as wide as it was at the low point of prices in 1932.

Production trends indicate that butter may not retain even its present not particularly favorable price position. There were 14 percent

FIGURE 17.—Farm and parity prices of butter.

more milk cows on farms in June 1933 than in June 1928. The increase resulted from various causes, including low feed prices, a large supply of farm labor, and relatively favorable dairy prices. It is probable the turning point in milk-cow numbers will not be reached for about 2 years. Meantime the butter market will be constantly burdened with surpluses.

Production control, though difficult, is an essential part of the recovery process. The number of farms involved is very large. Milk production capacity is increasing, furthermore, because beef prices are very low and beef men are milking more cows and weaning the calves earlier. These difficulties merely emphasize the necessity for action. Satisfactory returns for butter depend on production adjustments and on continued improvement in demand conditions.

Cattle

Cattle prices declined sharply and steadily in 1930, 1931, and 1932 despite the fact that slaughter supplies during that period were relatively small. Prices declined further through 1933 as slaughter increased sharply after April. Cattle numbers at the beginning of 1933 were about 15 percent larger than 5 years earlier. Cattle production has been in the upward phase of the characteristic cycle since 1928. It is probable that increase in numbers will continue at least through 1934 and that slaughter will continue large for several years.

Cattle prices during the first 9 months of 1933 were at the lowest levels in more than 25 years. Cattle producers did not share, to any extent whatever, in the rise of purchasing power enjoyed by other branches of agriculture. For cattle producers the immediate prospect is relatively unfavorable. Cattle feeders next year may do better, since unfinished cattle are selling at extremely low prices—for some kinds the lowest on record—and cattle feeding will be reduced. The present low prices tend to restrict marketings. Working in the opposite direction, however, is the shortage of feed in many areas, and the pressure of debt on many cattlemen.

Supplies of beef for consumption are large at a time when consumer purchasing power is at a very low ebb. Recent months have seen a moderate improvement in the consumer demand for meats. Further improvement depends on a continued increase in consumer buying power. Prospective reduced production of competing meats may

FIGURE 18.—Farm and parity prices of cattle.

strengthen the demand for beef somewhat during 1934, but this will be offset to a considerable extent by the expected increase in slaughter supplies of cattle.

Lambs

The sheep industry of the United States in 1933 was in the second year of the down swing in the present production cycle. Lamb prices in 1933 were somewhat higher than in the previous year, but this price gain for the season was due entirely to the sharp increase in wool prices. Prices of dressed lamb in 1933 were below those of 1932. Further improvement in business conditions will probably advance lamb more than wool prices.

Prior to the depression of 1929, lamb prices were relatively high. Indeed, the sheep industry as a whole enjoyed high prosperity from 1922 to the end of 1929. Its gross returns for 1929 exceeded those of any previous year in its history. In 1930 the trend turned downward, and in 1931 lamb prices fell to the lowest level in many years. Prices of slaughter ewes dropped to the lowest level on record in the fall of 1931. In the first 9 months of 1933 the market improved somewhat. The average price of sheep and lambs slaughtered under Federal inspection during November 1933 was \$6.20 a hundred pounds as compared with \$5.14 in the corresponding month in 1932.

It is not likely that the present downward trend in sheep numbers will continue long. In previous sheep-production cycles the down trend has varied from 3 to 6 years. This down trend seems likely to be a short one, because the present position of the western sheep industry as regards land ownership, range control, and grazing allotments favors reexpansion, if wool prices continue at or near present levels and weather and feed conditions make this possible. Under such condi-

FIGURE 19.—Farm and parity prices of lambs.

tions, numbers would show an increase by the end of 1935. The western sheep industry has had very unfavorable operative conditions for several years. In the natural course these conditions will change, and with them the volume of lamb production.

Wool

Wool prices declined from 1928 to 1932. At the low point in July 1932 the average farm price was only 40 percent of the 1909-14 average.

FIGURE 20.—Farm and parity prices of wool.

age. Prices advanced sharply in 1933 to a point well above the pre-war price. This recovery reflected a marked increase in domestic manufacturing activity, rapid movement of the domestic clip, and

strength in foreign markets due to the depreciation of American exchange in foreign trade, and the prospect of reduced world wool production. Sheep numbers in most of the important wool-producing countries are now declining, following 5 years of expansion. Drought in 1933 in several countries of the Southern Hemisphere foreshadows a further decline. World wool prices, as well as prices in the United States, advanced. The early advance in domestic wool prices, however, was greater than the advance in foreign wool prices in terms of United States currency, and during the third quarter of 1933 the margin of domestic wool prices over foreign wool prices widened sufficiently to permit imports of substantial quantities of most grades of wool.

The consumption of wool by United States mills, after a sharp increase last spring, has been maintained at a relatively high level. However, it will require a substantial increase in consumer incomes to maintain a level of activity in 1934 comparable to that of the last half of 1933. It is significant of the strong position of this commodity, however, that wool prices held up well during the fall of 1933, when prices of other commodities were declining. Since present supplies of domestic wool are reported to be relatively small, a high rate of mill activity during the early months of 1934 would make increased imports necessary. The movement of wool prices in foreign countries and monetary developments in this country and abroad will therefore continue to exert considerable influence upon the trend of domestic wool prices.

Chickens

Unlike the experience of most other farm commodities the relatively high level of farm prices was maintained during the depression years of 1921 and 1922. In the years between 1924 and 1929 the spread between the farm price of chickens and the parity price was increased in

FIGURE 21.—Farm and parity prices of chickens.

favor of the poultry producer. These were years in which the level of consumer incomes was generally high and resulted in an increased demand for poultry. Following 1929, farm chicken prices declined and fell below parity in February 1932, after which date the disparity between the farm price and the parity price continued to increase. In October 1933 the farm price of chickens was 9.3 cents per pound. This was 3.9 cents, or 29 percent, below parity.

Farm chicken prices failed to respond to generally rising price levels during the spring and summer of 1933 to the same extent as did most other farm commodities, largely because of heavy marketing and large supplies of other meat products in storage.

Storage stocks of dressed poultry on October 1 were slightly above average as a result of heavy marketing during the summer and early fall. By November 1, however, the stocks were less than average for the past 5 years, while receipts at the four principal markets, New York, Chicago, Boston, and Philadelphia, continued heavy, and market prices declined.

Horses and Mules

Horses and mules have been low in price for many years, mainly in consequence, as is well known, of the substitution of mechanical for animal power on farms and in cities. It seems now that the need for work stock may shortly exceed the supply. In fact, there may soon be

FIGURE 22.—Farm and parity prices of horses.

a serious shortage of work stock. Acreage-reduction programs sponsored by the Federal Government will lessen the farm need for horses and mules, but overbreeding is extremely improbable.

Horses on farms in January 1933 numbered 12,163,000, only 57 percent of the number reported on January 1, 1918. Mules on farms in January 1933 numbered 4,981,000, only 84 percent of the number on farms in 1925. In cities, towns, and elsewhere, the decrease in the numbers of horses and mules has been relatively much greater than on the farms. According to estimates based upon partial returns secured by the census, the number of horses not on farms in 1930 was about 300,000 head, and of mules about 75,000 head. These figures compare with a census estimate of 3,183,000 horses and 270,000 mules not on farms in 1910. Present conditions make tractors, gasoline, and oil relatively high cash-cost means of farm power. Accordingly, many farmers on the small and moderate-sized farms are again depending on horses for their power. In October 1933 the prices of farm horses in some markets were as much as \$25 a head higher than in October 1932.

Future requirements for work stock on farms will depend on whether the use of mechanical power increases or decreases and on the acreage in cultivation. Renewed prosperity would make possible an increased

use of mechanical power. Under present conditions many farmers cannot buy replacements, repairs, and fuel. On the other hand, substantial contraction of acreage in crops would reduce the need for power and perhaps make it possible for many farmers to operate only with work animals. In any event, however, the outlook for some years is for a short supply of work animals in relation to the demand. Only expanded raising of both horse and mule colts can check the present decline in numbers of these animals and could not prevent a further decrease in animals of working age until some years had elapsed.

Potatoes

Because the demand for potatoes does not change greatly from year to year, small crops consistently return higher gross incomes to farmers than large crops. The crop of 318,000,000 bushels in 1933 was the smallest since the small crop of 1925. Yet growers will get from it a

FIGURE 23.—Farm and parity prices of potatoes.

gross income almost three times that which they received from potatoes grown in 1932. The small crop resulted mainly from poor growing conditions. Acreage was not below the average.

It is expected that the high price received for the 1933 crop will cause growers to increase their acreage. Ordinarily about 3,000,000 acres will produce an ample supply of potatoes for human consumption in the United States. Average growing conditions on more than 3,000,000 acres will give a total crop considerably in excess of normal consumption requirements and will return the growers a much smaller gross income than that received for the 1933 crop, but probably somewhat above the low returns of 1931 and 1932.

Potato consumption in the United States has gradually declined during the last 10 years. Good prices received for a short crop, therefore, do not justify substantial increases in the potato acreage. Low prices in 1931 and 1932 caused heavy losses to many growers, particularly in areas distant from markets. In such areas the acreage declined. Growers located fairly close to markets, however, maintained their acreages almost up to the 1931 peak. To maintain their favorable

price relationships, potato growers need regional coordination of acreage adjustments and shipments to markets in line with demand conditions.

Sweetpotatoes

Sweetpotato growers received fairly satisfactory prices for their crops in 1933, after 4 years of declining prices. Sweetpotato prices rose in sympathy with the prices of potatoes, the crop of which was extremely short. Nevertheless, prices remained substantially below the pre-depression level. On November 15, 1933, the farm price of sweetpotatoes averaged 56.4 cents a bushel as compared with 37.7 cents in November 1932, and 93.8 cents a bushel in November 1930. Acreage devoted to sweetpotatoes varies sharply in accordance with the price received for the last crop. In 1932 growers got unusually low prices. Hence, the acreage of sweetpotatoes in 1933 was 12 percent below that of 1932. In the South Central States the decreases in acreage averaged

FIGURE 24.—Farm and parity prices of sweetpotatoes.

16 percent. The United States production in 1933 amounted to about 70,000,000 bushels.

An increased acreage of sweetpotatoes will probably result from the price gains of 1933, particularly where the crop is grown for the market. The acreage is likely to be somewhat larger also where sweetpotatoes are grown largely as a farm food crop. In the case of a crop subject to such large annual changes in the acreage, the trend over a period of years rather than the price in any one season should be taken as the measure of its profitableness. Prior to the depression sweetpotato production gave relatively good returns.

Beans (dry, edible)

The average farm price of beans in the United States followed the downward trend of agricultural commodities from 1929 to the early part of 1933. It rose sharply and steadily in 1933, and by August had almost attained the parity level. This was a recovery from the lowest point on record. From September 1931 to March 1933, bean prices were relatively lower than farm-commodity prices generally. The trade disappearance of dry beans during the 1932 crop marketing sea-

son was about a million bags less than the average disappearance for the preceding 5 years.

Unless consumption improves, any increase in general acreage, with average yields, would result in an increased surplus. Our production of beans in 1933 was 11,639,000 bags, judging by crop conditions on

FIGURE 25.—Farm and parity prices of beans.

November 1, and the carry-over (from previous crops) on September 1, in 1933, was about 1,250,000 bags. This total of over 12,000,000 bags was about 680,000 bags less than the average annual supply during the 5 years, 1927-31.

Eggs

Egg prices have been continuously below parity since November 1929. During 1930 the spread between the farm price of eggs and the parity price became increasingly wider until it reached the greatest

FIGURE 26.—Farm and parity prices of eggs.

disparity in February 1931, when the farm price was only 50 percent of parity. The condition of extremely low egg prices in February was repeated in 1932 and again in 1933 as a result of unseasonably mild

winter weather in the Middle West, and also because feed prices declined even more than did egg prices, both of which factors served to bring about an unusually large winter production.

In October 1933 the average farm price of eggs was 20.8 cents per dozen. This was 8.2 cents or 28 percent below parity. Light storage stocks of eggs in the fall of 1932, and curtailed production in the fall of 1933, caused egg prices to be nearer to parity during those two seasons than was the case in either 1930 or 1931.

Rapidly rising feed prices caused curtailed production of eggs during the fall of 1933, with the result that storage stocks of shell eggs moved into consumption at a very satisfactory rate.

Apples

For 20 years or more the apple industry of the United States has been under the pressure of economic forces tending to produce favorable readjustments. The depression found it well equipped for efficient production. It had a relatively large proportion of the better varieties, and its production was almost as heavy as it had been 20 years earlier,

FIGURE 27.—Farm and parity prices of apples.

when the number of apple trees in commercial orchards was twice as great. The depression speeded the readjustment process. Growers decreased tree plantings, removed trees of odd varieties, and concentrated new plantings in the more popular varieties. A shift from farm to commercial orchards, which started many years before, continued. Curtailment of production expenditures reduced the bearing capacity of the orchards. In consequence, apple prices showed more strength than the prices of some other orchard crops.

Apple growers have to contend, however, with heavy competition from other crops, and this competition will probably continue in United States markets. The production of oranges, grapefruit, peaches, pears, and grapes, and imports of bananas, increased 50 percent from 1919 to 1933. Meantime, European countries are modernizing their fruit industries and erecting trade barriers which narrow the export outlet for American apples.

Apple prices in 1933 averaged higher than in 1932. On November 15, 1933, the United States farm price was 73.1 cents a bushel, as com-

pared with 57.1 cents in November 1932, and a November average of 75.5 cents for the years 1910-14. Apple prices in this country depend in part on the world market. Our yearly exports range from 12 to 20 percent of the commercial crop, and any serious check to the export movement reacts at once on domestic prices. In 1933 the total apple crop of the United States was about 144,000,000 bushels. The average production in the 5 years 1926-30 was 168,773,000 bushels. This decline, however, does not necessarily indicate that the supply situation has been permanently improved. Orchards are now below normal bearing capacity, and could be rather quickly brought back to normal under the stimulus of increased business activity and increased production expenditure.

Tobacco

Since 1930 the price for practically every kind of tobacco has remained well below parity. The average price for all types fell from 80 percent of the parity level in 1930 to 60 percent of that level in 1931. In 1932, however, due to the reduced crop, prices for every class of

FIGURE 28.—Flue-cured tobacco; parity and actual prices, 1920-33.

tobacco except cigar leaf showed improvement, and the average of all types was 20 percent below parity. Prices for cigarette tobaccos were helped somewhat in 1932 by the unusual demand condition caused by low-priced cigarettes. Already prices for some types of the 1933 crop have been lifted by the adjustment program, but the extent of this effect is shown only for flue-cured. These types are selling at prices about 50 percent higher than last year. It is estimated that the production-adjustment program and the marketing agreement between the Secretary of Agriculture and leading buyers has lifted the average price for the entire flue-cured crop at least one third. The amount paid growers for this crop, together with benefit payments to be made within the current marketing year, will bring average receipts per pound to a figure approximating the present parity for this tobacco.

The post-war base period for tobacco, August 1919 to July 1928, was chosen by Congress. Wide differences exist between the 25 types of tobacco grown in the United States. To facilitate the adjustment of supplies to consumption, the Administration deemed it advisable to

class these types as commodities—cigar leaf, flue-cured, burley, fire-cured, dark air-cured, and Maryland tobaccos.

The supply of most kinds of tobacco is excessive, owing largely to decreased world consumption. However, burley supplies are at record levels because for each of the last 5 years, production has exceeded the consumption, which has changed very little. For cigar-leaf, fire-cured, and dark air-cured tobaccos supplies are very large in relation to the present low world consumption. Stocks of these types are excessive in relation to needs, since production has not fallen enough below the amount used for holdings to be brought in line with the lowered consumption.

Drastic declines in foreign consumption of our flue-cured, fire-cured, and dark air-cured types have taken place since 1930. Though foreign consumption of flue-cured tobacco still remains 25 percent above that of a decade ago, it has declined around 30 percent from the level of 1930. Other countries now consume about 50 percent less of our fire-cured types and about 75 percent less of our dark air-cured tobacco than they did 10 years ago. These types have been displaced largely by competing foreign-grown tobacco. Exports of most types have been larger in recent months than for the same months of the previous year. The assurance of a smaller crop in 1934 and the Government's monetary policy appear to be contributing to the increased export movements from the 1933 crop.

Total United States consumption of tobacco declined only about 10 percent during the depression. The greatest declines occurred in cigars and chewing tobacco. The consumption of these products, which followed downward trends for a number of years, has declined sharply since 1930. The phenomenal increase in the use of cigarettes which took place after the World War, was halted in 1930. Though the consumption of cigarettes in 1933 was 10 percent higher than in 1932, it was still 7 percent below the predepression peak. The consumption of smoking tobacco increased during the depression, but not sufficiently to affect the decline in cigarettes.

This chart differs from the other charts given herewith in that it does not have the scale showing parity prices and actual prices as percentages of the pre-war base prices. In this case the base prices are for the period 1919-28.

LOUIS H. BEAN, *Economic Adviser, Agricultural Adjustment Administrator, and*

ARTHUR P. CHEW, *Assistant to the Director of Information, with the cooperation of the Bureau of Agricultural Economics.*

AGRICULTURAL Adjustment Methods and procedures of the Act Rests on Working of Agricultural Adjustment Act Established Economic Law rest on a recognition of the actual workings of the so-called

law of supply and demand. Previous farm relief legislation failed because it did not cope with the fundamental difficulties of controlling excessive supplies, removing inefficient marketing methods, and improving general purchasing power. The Agricultural Adjustment Act goes directly to two of these basic difficulties—unbalanced production and expensive marketing. The allotment scheme for controlling production was devised not only to remove the current surpluses, but to

bring about a stable agricultural output as called for by domestic consumption requirements and the altered conditions of foreign demand. It is essentially a method of altering the supply-and-demand factors so as to have the law of supply and demand work primarily to the benefit of the producers and to promote the general welfare by removing maladjustments as between prices and incomes. The allotment plan recognizes the necessity of compensating producers for action which on an individual basis they would not undertake. It also obviates the economic difficulty that arises from the existence of a group of nonparticipating producers, for the allotment plan is so devised as to compensate participating producers by payments which are in addition to the local prices obtained by nonparticipants. As a result, farmers who cooperate in reducing production can receive more income from the reduced output than the noncooperators receive from their maintained output. This should induce nearly all farmers to participate in production control.

It would be possible to levy a tax and disburse the resulting funds to farmers as benefit payments without any accompanying control of production. Under certain conditions such operations would increase farmers' incomes. The possibilities of the method are materially different as between products some of the supply of which are exported and products which are sold entirely on the domestic market.

When control of production is combined with the collection of tax and disbursement of benefit payments, farmers may receive long-time benefits in reduction of excessive supplies and general advance in the level of prices, even if the value of the crop for the current season were not increased. This is particularly true of nonperishable crops, where excess supplies from 1 year pile up and act as a depressing influence on prices for a long time thereafter. As is evident from the following discussion, however, the current income from crops such as wheat and cotton would be increased even if there were no accompanying control of production; the fact that under the Agricultural Adjustment Act both methods are combined to make the potential advantages of the method all the greater.

Effectiveness of Processing Taxes

The tax on the domestic processing of individual farm products as specified in the act may serve two purposes: (1) To provide funds for the payment of benefits to farmers for control of production, and (2) to produce more income from the commodity than would otherwise be received.

In those cases where the imposition of the tax, together with other arrangements makes possible effective control of production, the processing tax may be worth while even though the combined income from sale prices and tax is no larger than would be received in the absence of a tax. The tax may be still more effective, however, if it not only provides funds for control of production but also directly produces a larger net income for the same quantity of product.

Varying Effectiveness of Tax on Different Products

Although the processing tax is to be collected from the processors, that does not necessarily mean that the full amount will be paid by the processors themselves. In paying the tax, the processor may derive

the necessary funds from three sources: (1) Charging higher prices to consumers, (2) paying lower prices to producers, or (3) operating on lower margins.

The extent to which prices to consumers can be raised depends upon the consumers' willingness and ability to pay a higher price without reducing purchases. In some commodities, such as bread and fluid milk, differences in retail price apparently have little bearing on the quantity consumers will purchase. In such cases, the processing tax may be in large part passed on to consumers without material reductions in the quantity that they will purchase.

The extent to which the processing tax can be passed back to farmers, in paying them a smaller price for the product purchased, is partly determined by the ability of farmers to resist such lower prices. Over a long period, farmers can resist by reducing supply. Once a given crop has been produced, however, farmers can resist only by diverting part of the supply to other markets than those provided by domestic processors, or by refusing to sell at all. For products such as wheat or cotton, the ability to sell on foreign markets may strengthen the farmers' resistance. The extent and effect of this resistance depends on the readiness of foreign markets to take increased quantities without serious price concessions. For some commodities, such as cotton, there may be a marked expansion in the quantity which can be sold abroad as a result of a relatively slight decline in price. In such cases, farmers are in good position to resist efforts to reduce the prices paid them, since they could readily dispose of additional quantities of products abroad.

Finally, part of the tax might be absorbed by reducing the margin received by processors, and marketing and distribution agencies. These agencies cannot reduce their costs below that required to cover their current cash outlays without eventually being forced out of business. On the other hand they can operate over considerable periods without the same return on their investment as they have received in the past. The profits earned by corporations engaged in this field have shown less reduction during the period of the depression than those of other corporations, and in some cases have even increased. This indicates there may be real possibility of absorbing part of the tax through reducing the margin taken for distribution.

During periods of declining prices, the changes in wholesale prices tend to lag behind changes in the prices for raw materials, and changes in retail prices tend to lag behind changes in wholesale prices. Distributors' margins widen, or at least do not shrink as fast as they otherwise might shrink. The imposition of the processing tax reverses this process by creating a condition where the cost of raw materials to the processor tends to increase. Since, ordinarily, wholesale prices do not increase as rapidly as the cost of the raw materials, and retail prices do not rise as rapidly as wholesale prices, the tax may exert a definite tendency toward reducing the margin.

This appraisal of the ways in which the tax may be borne indicates that portions of it may be absorbed in each of the three ways dependent on the conditions in the particular commodity. The final result for any commodity would depend on the net balance among the effects in all these directions.

Applying the Tax on Cotton

If a tax of 4 cents per pound were imposed on the domestic processing of cotton, that would tend to reduce the domestic consumption. Even if the entire 4 cents were passed on to domestic cotton purchasers, however, it is unlikely that this much advance in cost would reduce the domestic consumption by more than half a million bales. In the absence of production control, it would be necessary to add that half million bales to the quantity to be disposed of in foreign markets. Foreign markets are much less sensitive to changes in cotton prices than are domestic markets, however; so this additional half million bales could be added to exports without causing much of a drop in world price levels. Preliminary estimates indicate that a 4-cent tax, with no change in production, might reduce the world price level something less than 1 cent per pound, and increase the cost of cotton to domestic consumers (tax included) by something more than 3 cents per pound.¹ The gain of over 3 cents on the 40 percent of our cotton production which goes into the domestic market would much more than offset the loss of less than a cent on the 60 percent which goes into foreign markets, and the net income from the whole crop would be materially increased in consequence.

The ability of such an operation to increase the net return from the product depends upon three factors: (1) The responsiveness of domestic consumption to change in price; (2) the responsiveness of foreign consumption to change in price; and (3) the proportion of the total domestic product which may move into export.

In the case of cotton, where more than half of the total is exported, the operation would not bring a net gain in income from domestic cotton production if it were not for the fact that domestic demand for cotton is less elastic than is foreign demand. Withdrawing a given quantity of cotton from domestic consumption and adding it to the quantities disposed of in foreign markets results in a much greater increase in domestic prices than a decline in world market prices.²

In commodities such as wheat, where a small proportion of the crop is exported, and where our exports contribute a small percentage of the total world supply, the probable gain in income would be much greater. The additional price would cause only a negligible decline in domestic consumption; and the addition of this quantity to export would have only slight influence on world prices, even if no effort were made to reduce production. Such a commodity offers an almost ideal situation for the operation of this plan to increase income to farmers.

Fundamentally, the domestic-allotment plan enables the quantity sold on domestic markets to be adjusted at such a level as will bring in a fair return from the domestic use of the product, even though the rest of the product is being sold for foreign use at the lower price prevailing in foreign markets. During the period while processing taxes are imposed, it guarantees to cooperating farmers that the market price plus the benefit income will bring them a parity price on that part of their production which is needed for domestic consumption. The plan offers them a protected price on their allotted share of the domestic consumption—hence the term “domestic allotment plan.”

¹ These estimates are rough first approximations, but are based on the price data readily available. More exact estimates could be obtained from more elaborate examination of all the elements in the case, using the results of such precise studies as that reported in Technical Bulletin 50.

² If, at the same time, production were to be reduced by an equal or even larger amount, the world market price would not be forced down at all, and the entire effect of the reduction would be concentrated largely on domestic markets.

Application of Tax on Domestic Commodities

On domestic commodities the tax would primarily facilitate the control of production, but would not of itself provide increased farm income. In the case of a commodity such as butter, which sells ordinarily entirely in the domestic market with no export movement, the situation is quite different. Here there is no possibility of the farmers resisting the reduction in the farm price by diverting part of their supplies to foreign sale. The only way in which the imposition of the tax, without production control, may lead to increased income in the hands of the farmers is by increasing the price paid by consumers or by reducing the margin taken by distributing agencies. So long as the same supplies are forced on the markets, presumably consumers would pay only the same price. Only to the limited extent that distributing costs would be reduced would the imposition of the processing tax on such a commodity increase the total income which will be derived from such commodity.

It might be worth while to impose a processing tax on a product such as butter or beef cattle, merely for the sake of securing funds with which to control volume of production. Such cases offer a less promising field for increasing income through the processing tax than do those commodities such as cotton and wheat, where the balance of economic responses in domestic and foreign markets is such that even in the absence of production control a net gain may be made in farm income from the commodity, through the modification of pricing practices which would result from the application of the tax.

Reduced production does not increase income for all products. For products sold entirely on the domestic market, the utility of the processing tax lies largely in its producing the funds to bring about a reduction in the supply. This involves several further problems. (1) Is it true that for all farm products the larger the volume produced the less the income the farmers receive? (2) Even if it is true, is it to the social welfare to increase farmers' income by starving the consumer or otherwise forcing him to pay high prices?

The data available indicate clearly that for some products, such as potatoes, a given change in the volume of the crop will have a far more than corresponding change in the price on the domestic market. For such crops a crop no larger than the average or possibly slightly smaller than the average will return far more income to farmers than will crops much larger than the average.

One reason for this condition is that when supplies are unduly large prices fall to the point where farmers feed some of the crop to livestock or leave it undug to dispose of the whole crop. This is particularly true of crops of large bulk or relatively low value per pound so that transportation and marketing costs may absorb the entire retail price in years of large production.

In the case of some other products, such as butter and cattle, there is far less response to change in prices than is true in case of potatoes. For these two products a small supply will apparently sell for somewhat more than a large supply. The difference is, however, less pronounced than in the case of potatoes.

For still other products, especially semiluxury products such as some of the higher-priced fruits and vegetables, and also for specialty products such as peanuts, the data available indicate that a 10-percent increase in production causes less than 10 percent decline in wholesale

or retail price. Under such conditions, a large crop may bring in more gross income than a small crop.

In all of these cases, of course, the question of cost has been ignored. Even though a large crop of peanuts may sell for more than a small crop, it may be that it costs the farmer enough extra in the way of additional harvest labor and other expenses so that he nets no more from the larger crop. As a whole, however, the proportion of total cash costs which varies with output is sufficiently small so that the gross income from the product may be taken as at least a rough approximation of the effect of changes in the production of the product on income of the farmer.

It is evident that reduction in the volume of production is not a universal answer to the problem of how to secure higher farm returns. For some products, such control of production may bring in materially increased returns; for other products it may produce an incidental increase in returns; and for still other products, control of production may actually reduce gross income. Furthermore, there are marked limitations to what may be done to increase farmers' income under any conditions so long as demand conditions remain relatively poor. With any given level of demand conditions there are thus definite limits to the effectiveness of production control as a way of raising farm incomes.

Social Benefit of Balanced Output

A certain degree of restriction of production may be desirable from the point of view of the general welfare. When farm products are produced in such abundance that the retail prices do not even pay the cost of moving them to market, and the excess is permitted to rot in the fields, such surpluses are of no value to anyone. In such cases, it is clearly to the general good to save the additional effort involved in producing the excess supply. Even where such physical destruction is not involved, the attempt to force exceedingly large supplies of cotton or wheat or hogs into consumptive channels may press prices so low that farmers' buying power for industrial products is largely eliminated. Under such conditions the inability of farmers to buy and the resulting disturbance of the normal exchange of farm products for city products may result in such a serious break-down in industrial economic activity that the city loses far more through reduced employment and general economic depression than it gains from the resulting low prices for cotton or wheat or meat.

What is needed is a balance between the production of various products and the quantities which the markets can absorb at reasonable prices and with sustained activity on the part of industry as a whole.

One further element is involved. Although the demand for individual food products is elastic in varying degree, the maximum demand for food products as a whole is quite inelastic and depends on the size of the population plus the export market. The human stomach sets the limit to the quantity of food we can use; and the area of our skin tends to set a limit to our need for textiles. There are growing uses of farm products in industry, it is true, such as fountain pens made from the casein of milk or auto tires made from cotton and rubber; but such uses of farm products are slight compared to the basic uses for food and clothing. The substitution of mechanical power for human muscle, and of heated houses for heavy clothing, has actually caused a reduction in our per capita consumption of food and clothing. There have

been shifts between products, of course, as more dairy products and vegetables and less wheat and potatoes; but even including the increasing industrial uses our consumption of farm products seems to be growing no faster than our population, and probably not even quite so fast.

The limited demand for farm products makes it clearly in the general welfare that only so much farm products should be produced as are needed, either for the export market or to maintain adequate supplies for domestic requirements; and that which is produced should be in the proper balance between commodities.

It would clearly be contrary to the general welfare for farmers to be permitted to reduce the production of essential products to such a great extent as would result in famine conditions and corresponding scarcity prices for products even though such prices should produce unusually high farm incomes. There is no danger of such a contingency under the Agricultural Adjustment Act, however. As indicated in that act, processing taxes can be used only so long as the prices of farm products are below their normal relation to prices of other products. As soon as that parity has been established, the processing taxes will not apply in subsequent seasons. The act, therefore, completely prevents any extreme monopolistic practices on the part of farmers, through the control of production or otherwise.

Marketing Agreements

Marketing agreements, as provided for in the act, can reduce distribution costs, regulate market supplies, increase prices to farmers, yet protect public interests. Through voluntary agreements with associations of producers, processors, and dealers, and with the Secretary of Agriculture as a party to the agreements acting in behalf of the public welfare, it is possible to make considerable progress toward more efficient marketing. They open up opportunities in many directions for the general welfare.

Market gluts that destroy values both at the farm and at central markets can be prevented through agreements that prorate shipments according to current market requirements, and leave the nonmerchantable portion of the crop to be distributed either through relief channels or in other ways, so as to bring about a wider consumption without having the surplus portion of the crop threaten the value of the entire crop. Price demoralization that arises from the marketing of low-grade products in years of bumper crops can be prevented.

Marketing agreements may also be utilized to remove a large variety of unsound trade practices that contribute neither to the welfare of consumers nor the producers.³

Advertising programs which under present conditions serve largely to shift the volume of business done from one firm to another without actually expanding consumption, can, under the voluntary marketing agreements, be made to serve the interests of all producers and the distributing agencies as a group. Advertising expenditures may result in a larger total volume of consumption by emphasizing the essential characteristics of a product and its place in a higher standard of living. Such advertising can reasonably be expected to contribute toward reducing marketing spreads per unit. Advertising which bases its appeal

³ UNITED STATES DEPARTMENT OF AGRICULTURE, BUREAU OF AGRICULTURAL ECONOMICS. UNFAIR PRACTICES IN THE MARKETING OF AGRICULTURAL PRODUCTS. U.S. Dept. Agr., Bur. Agri. Econ. Library. 13 pp. Aug. 25, 1933. (Typewritten.)

on imaginary qualities that the article never possessed, or on emotional appeals, may lead to competitive struggles for volume which increase selling costs without any corresponding advantage to producers or consumers. Such practices might be modified by suitable marketing agreements.

Lowering Marketing Costs

Similarly, voluntary agreements open the way for reorganizing inefficient high-cost distribution facilities, in the interest of lowering the costs of marketing. Agencies entering into an agreement with the Secretary of Agriculture may undertake to retire high-cost inefficient services and to encourage the expansion of low-cost services in the interest of a greater volume of distribution, relatively lower costs to consumers, and a larger share of the consumer's dollar for the farmer.

Furthermore, marketing agreements can be utilized as a direct means of securing more adequate prices to producers. Where definite control of total supplies can be established either through prorating shipments among dealers or limiting the volume to be processed, agreements may provide for prices to producers and to distributors in accord with supply-and-demand conditions, provided most of the producers and primary distributors or processors participate in the agreement. Price fixing under these circumstances becomes economically feasible, since important elements which determine prices are brought under control. In these cases, however, the price improvement which can be secured through these agreements is limited to that which can be exerted through changes in supply and greater efficiencies in marketing, since these agreements offer no direct means of increasing effective demand for the product (except possibly to a limited extent by diverting excess supplies to relief channels).

The Agricultural Adjustment Act provides for direct efforts at improvements of marketing methods and reduced costs of distribution. Through voluntary agreements with the Secretary of Agriculture, the act makes possible the elimination of trade practices by group action which no individual distributor could undertake and which might be contrary to the antitrust laws if attempted by private agreements. By means of voluntary agreements under the Agricultural Adjustment Act, it is possible to prevent the losses to producers, distributors, and consumers that arise from the marketing of bumper crops beyond the requirements of consumers. Through marketing agreements it is possible to recognize the principle that reduced costs which result from the establishment of more efficient marketing practices should redound to the benefit of producers, distributors, and consumers. They are also predicated on the sound economic principle that prices to growers, distributors, and consumers can be established at basic levels for each group consistent with existing conditions of consumer purchasing power; provided there are the requisite definite arrangements for carrying through needed readjustments in marketing organization, structure, and pricing methods.

Many of the problems in distribution already discussed, which tend to reduce the farmers' share of the consumer's dollar, cannot be adequately solved without the centralizing power of a Government agency.

The Agricultural Adjustment Act provides for the removal of surpluses through means other than direct reduction of production. By the use of a portion of the processing taxes, surpluses may be removed by the elimination of domestic underconsumption and by the expan-

sion of markets, as well as by the reduction of acreage. The flexible provisions of the act permit the setting up of marketing agencies to dispose of surpluses among the millions of domestic unemployed consumers and to dispose of surplus crops abroad without affecting the usual currents of domestic or foreign trade.

Influence of General Recovery

The efforts to increase agricultural income will help, and will be helped by, general economic recovery. Agricultural income and general purchasing power are definitely interrelated. For certain branches

FIGURE 29.—Money income of industrial workers and farm income, 1919 to September 1933. Farm income and industrial-consumer incomes are basically interdependent; at certain critical points, however, farm income may either decline (as in 1919-20) or rise (as in 1921-22) before the similar changes in consumers' incomes. The prospect for foreign demand at the end of 1932 was not at all favorable. A rise in farm income if produced by reductions in surplus supplies would assist in promoting general recovery as in 1921-22, when domestic crops were reduced, and in 1924-25, when foreign demand was stimulated by reduced crops abroad.

of agriculture, world-demand conditions may at times bring about an increase or decrease in farm income, but the major portion of farm income is so intertwined with the national income that it is statistically difficult to treat them separately and to measure the influence of one upon the other. For example, during most of the period 1921-32, the changes in farm income have paralleled the changes in the money income of industrial workers (fig. 29). At certain critical periods, however, improvement in farm income preceded and supported the revival in consumer incomes. During the last half of 1921, the volume of industrial activity had begun to advance, but money incomes of industrial workers remained at their low levels until the spring of 1922. Farm income, however, largely as a result of curtailed supplies of cotton and other crops, rose sharply during the winter months of 1921, thus aiding the progress of revival. Again in 1924 when industrial activity was declining and consumer incomes were being reduced, a sharp advance in farm income, this time due to favorable foreign-demand conditions growing out of a small world wheat crop, helped to check the business recession and bring about business revival.

Similar beneficial influences could reasonably be expected to result from the operations of the Agricultural Adjustment Act, as bases are laid for higher prices through reductions in current or prospective supplies. The control of production and elimination of surpluses can contribute to general industrial recovery and increased consumer incomes through its effect on prices. The rise in farm prices through actual or potential reduction in acreage and production, insofar as it enhances the inventory value of surpluses, strengthens the credit structure, and gives farmers a greater income, and spreads purchasing power. The distribution of benefit payments through advances to producers before processing taxes are collected, creates a fund of purchasing power that serves to promote revival in the same way as a similar extension of credit in actual use. Increase in agricultural income may thus serve to expand other incomes as it did in the 1921-22 revival.

The dependence of farm income on the national income, once the broad forces of revival are well in motion, naturally serves to emphasize the restricted field of influence on prices that may be exercised by the operations of the Agricultural Adjustment Act. The level of prices at the farm is controlled by several factors—the volume of production, distribution, and processing costs and charges, consumer purchasing power, and monetary changes. The operations of the Agricultural Adjustment Act can go a great way toward raising prices through the reduction of supplies, and it may increase farm returns through reducing certain distribution and processing costs, and removing unfair and inefficient trade practices. In cases where these distribution and processing charges are determined largely by transportation rates and industrial wage levels, benefits to farmers from marketing agreements will depend very largely on the extent to which industrial wages and transportation rates respond to current depressed conditions. The operations of the Agricultural Adjustment Act cannot, of course, restore that portion of the fall in farm prices which is due to monetary policy and to consumer incomes, except as improvement in the latter is the outgrowth of benefit payments to farmers. For complete restoration of pre-war parity prices, the removal of surpluses must be accompanied by other action aimed toward expanding employment and consumer incomes, and bringing about more nearly normal relations between various prices and services.

Other Factors in Recovery Program

The Agricultural Adjustment Act is an integral part of the whole recovery structure. It is one of the several measures that have been adopted to expand purchasing power of consumers. The National Recovery Act, which was enacted shortly after the Agricultural Adjustment Act, is intended to raise pay rolls through the elimination of sweatshop wage conditions, through balancing increased efficiency with shorter hours so as to decrease unemployment, to coordinate and control business activity so as to create a freer and stable flow of purchasing power. The Public Works Administration was organized to expand purchasing power by undertaking activities which call for a great outlay of materials and wages, so that the latter might enhance the demand for agricultural and other products of current consumption. The Farm Credit Administration was established so as to refinance farm mortgages and to provide other credit facilities to farmers at lower

interest rates and at better terms, with the purpose of releasing agricultural buying power for the current purchases of industrial products. The Home Loan Administration was similarly organized to help refinance and extend urban credit so as to release current purchasing power for the products of industry and agriculture. The Emergency Relief Administration was organized to provide temporary relief to the unemployed victims of this depression. This, too, provides for Federal, State, and local distribution of funds so as to give those on relief some measure of purchasing power. All of these recovery efforts are interrelated. Recovery calls for removing agricultural-price disparities and increasing farmers' purchasing power, wiping out unemployment, expanding industrial production, restoring incomes to city workers, creating a demand for raw materials of agriculture, mining, and manufacturing, and so bringing about a general business revival on an enduring basis. The Agricultural Adjustment Act and the other recovery measures are thus fundamental in promoting a lasting and self-sustaining general recovery.

MORDECAI EZEKIEL, *Economic Adviser to the Secretary of Agriculture*, and

LOUIS H. BEAN, *Economic Adviser, Agricultural Adjustment Administration*.

APPLE and Pear Export Act Promises Important Benefits to Producers

The Export Apple and Pear Act, approved June 10, 1933, is designed to promote the export of apples and pears from the United States, to protect the reputation of these American-grown fruits in foreign markets, to prevent deception or misrepresentation as to their quality when moving in foreign commerce, and to provide for the official inspection of these products before they enter foreign commerce.

There has been a steadily increasing tendency on the part of foreign governments during recent years to restrict the importation of American fruits in various ways. In some instances only fruits having certain quality may be imported during certain periods. In other instances there has been increasing rigidity of sanitary requirement and inspection. Great Britain now prohibits the importation of the lower grades of American apples between July 1 and November 15 of each crop year. The higher grades of apples, which are allowed entry, must be practically free from apple maggot. There is no British regulation or order excluding fruit infested with this insect, but representations had been made to this Government concerning the undesirability from the British point of view of importing such fruit. To avoid an embargo or other official restriction which appeared imminent, it was necessary to provide some authority under which uniform and universal inspection of export shipments could be made. The voluntary inspection service of the Department could be made effective only with the cooperation of all the shipping interests, which obviously would not be obtained, for at times the British market was so much better than the American for certain varieties and sizes that uninspected lots were certain to be exported.

It is probable that the failure of some exporters to cooperate with the United States Department of Agriculture and the steamship lines in a voluntary plan to prevent the exportation of infested fruit was the

determining factor in winning the support of the industry as a whole for mandatory legislation.

Importance of the Export Trade

Yearly exports of fresh apples have ranged from 12 to 20 percent of the domestic crop in recent years. In the 1932-33 season we exported 13,800,000 bushels of apples, or about 16.1 percent of the total commercial crop, which was well below the average of the previous 5-year period. During the same season we exported 2,400,000 bushels of pears, or about 10.9 percent of the total crop. Recent yearly exports of pears have ranged from 6 to 11 percent.

It is easy to see that if our export market were closed the effect upon domestic prices would be disastrous. Furthermore, much of the export demand for apples has been for the smaller sizes which are least in demand in the home market. Thus the export outlet has reduced the pressure at the exact point best calculated to strengthen the home market. It is therefore highly important that the appearance and intrinsic quality of American fruits on foreign markets shall be such as to commend them and to give the general impression that they are desirable products, distinctly superior to the orchard run of local offerings.

Results Expected from the Act

The fruit trade believes that this action by the Government to limit exports to fruit of desirable quality and appearance will meet with the approval of foreign buyers and will tend to lessen the apprehensions of foreign governments.

It has been well known abroad that the Government of the United States assumed no responsibility for the character of fresh fruit exported and that it made inspections and issued sanitary certificates only to meet the requirements of specific foreign governments. The passage of the Export Apple and Pear Act marks a change in governmental policy in this respect. Hereafter, regardless of the requirements of foreign governments, the United States assumes responsibility for establishing minimum qualities of apples and pears that may be exported in carload lots to any foreign destination. The inspection of this fruit is no longer at the option of the exporter nor merely to establish those facts that must be determined to meet certain foreign requirements, but is universal and uniform as to the minimum requirements set up by our own Government. These requirements are sufficiently rigid to satisfy a majority of our important foreign customers.

Nature of Regulations Under the Act

The act provides that the Secretary of Agriculture may designate the conditions other than those of grade which the fruit must meet before it may be exported. Under this provision the regulations require:

(a) The packages shall be plainly and conspicuously marked with (1) the name and address of the grower or packer; (2) the variety; (3) the grade names not lower than those specified in regulation 5; and (4) the numerical count or the minimum size.

(b) Each package shall be packed so that the apples and/or pears in the shown face shall be reasonably representative in size, color, and quality of the contents of the package.

Another regulation provides that

no certificate shall be issued under this act and these regulations except upon a showing satisfactory to the Chief of the Bureau of Agricultural Economics that the apples and/or pears comply with the tolerances for spray residues established under the Food and Drugs Act of June 30, 1906.

The machinery already in existence for the inspection of fruit under the farm products inspection law has been utilized for the purpose of making inspections under this act. This enabled the Department to render the service wherever required from the moment that the act became effective.

Enforcement

The act forbids any common carrier to receive any apples or pears for a foreign destination unless accompanied by the official certificate required by the act. It is hoped that this provision will render the enforcement of the act almost automatic, for it is not believed that many common carriers, either by rail or water, will intentionally risk incurring the penalties of the act for the sake of transporting a few uninspected shipments in violation of the law. It is believed that a few violations that occurred during the first 60 days of the operation of the act may be charged to a lack of appreciation of the seriousness of the situation by certain local and minor officials of the boat lines involved. On the whole, the first few months of operation indicate that the act is entirely workable, salutary, and desirable.

WELLS A. SHERMAN,
Bureau of Agricultural Economics.

AVIATION Brings Foreign Plant Pests and Makes Quarantines Necessary

To the guardian of the horticultural interests of this country the airplane suggests another means of entry for plant pests. The development of fast ocean liners with improved refrigeration facilities, and more recently the use of the airplane for international travel, have made it possible to bring to our shores in a fresh condition many perishable fruits and vegetables, with the attendant pest risk, which heretofore were excluded by lack of transportation facilities. Fruits from the tropics of Central America and South America may reach subtropical Florida within a day or two from the time they are gathered. Brownsville, Tex., is only a few hours removed from Mexico City and Tampico, Mexico. Mountain ranges, deserts, oceans, and other natural geographic barriers which have tended to keep plant pests in their place, so to speak, for countless centuries have in effect been erased from the map.

In an effort to cope with this situation quarantines and restrictive orders prohibiting or restricting the entry of plants and plant products have been promulgated under authority of the Plant Quarantine Act of 1912. Plant quarantine inspectors engaged in the enforcement of these quarantines and restrictive orders are stationed at all important ports of entry, including landing fields for airplanes from foreign countries. Such plants, fruits, and vegetables as are permitted to enter are examined closely for the presence of plant pests (fig. 30). Baggage of passengers (fig. 31), ships' stores, crews' and passengers' quarters on ships, and airplanes from foreign countries are also examined by these inspectors for the presence of prohibited fruits, vegetables, or other plant material.

To the foreigner coming to this country or to the tourist returning home, the presence of a fruit or a plant or two in his baggage may seem of little consequence. Experience has shown, however, that a great many of the plants and fruits intercepted in such baggage actually harbor insect pests or plant diseases.

Interceptions at Airports

The importance which the airplane has assumed as a means of introducing plant pests is well illustrated by the inspection records for the fiscal year ended June 30, 1933. During that period a total of 3,427 airplanes was inspected at 10 ports of entry, and 626 interceptions of prohibited plant material were made. From this material 81 different

FIGURE 30.—Inspecting the interior of an airplane from Mexico at Brownsville, Tex., for the presence of prohibited plant material.

lots of insects were taken. Among the insect pests which have been intercepted in plant material brought to this country by airplane during the past few years are the citrus blackfly, a very serious pest not known to occur in the United States, larvae of injurious fruit flies, several species of scale insects, the pink bollworm, and many other insects which are of lesser importance.

When the *Graf Zeppelin* made her first trans-Atlantic voyage in October 1928, 7 species of insects and 2 plant diseases were found in bouquets of flowers which had been used for decorative purposes in the passengers' quarters. Again in August 1929, when this airship made her second visit to this country, 20 species of insects, 6 of which were not known to occur in the United States, were taken by plant quarantine inspectors from plant material found on board.

It is difficult to estimate the importance of such interceptions. Frequently insects or plant diseases which are considered as of limited economic importance in their native habitat suddenly become pests with great powers of damage when introduced into other countries where they are free from their natural enemies and where conditions in general are favorable for their multiplication. Excellent examples of this are the gypsy moth, the Japanese beetle, the oriental fruit moth, and the San Jose scale, insects which have been introduced from foreign countries and on which millions of dollars are spent each year in the United States in an effort to keep them under control. We might

FIGURE 31.—Inspection of passengers' baggage arriving at Brownsville, Tex., by airplane from Mexico.

note the chestnut blight as another example. Native chestnuts in Asia have a strong immunity against the blight, but when the disease reached this country it spread very rapidly, and in a few years it had practically destroyed all the native American chestnut trees from the New England States to the Carolinas.

It has been estimated that approximately 2 hours of each day's work on the farm or in the garden and orchard go to feed these uninvited, alien guests, and an even greater burden may be placed upon American agriculture should any of the additional pests which are now coming to the United

States by ship and airplane succeed in establishing themselves in this country.

F. A. JOHNSTON, *Bureau of Plant Quarantine.*

BANG'S Disease May Enter the Body Through Skin or Eye, Recent Studies Show

One of the most important facts to learn about a communicable disease is the route or routes through which it enters. This knowledge enables one to place obstacles in the way of the invading disease germs and to take other precautions to prevent them from entering the body. Without such knowledge one can do little more than guess at the best preventive procedures.

In the case of Bang's disease, or infectious abortion as it is also called, there was a popular belief for a long time that because the uterus

was the principal site of the disease, the germ causing it must enter this organ through the canal leading to the exterior. The germ was thought to be introduced by the bull at the time of service or later in some other way. Experimental proof, however, that this often happens has not been forthcoming. Though the bull in rare instances may infect cows directly by service, present evidence indicates that he is not an important means of spreading the disease unless his sexual organs are diseased. Even then he may spread the disease indirectly by contaminating his environment rather than directly through service.

Soon after the Danish investigator, Bernard Bang, discovered the causative organism, *Brucella abortus*, he found that it could be communicated to pregnant cows and heifers by placing infected material in their mouths. His results have been confirmed by numerous other investigators, and for a number of years the digestive tract was regarded as almost the exclusive channel through which infection took place. Although experiments have shown that it is a very important one, later investigations have indicated that cattle may become infected through two other channels, (1) the mucous membrane, called the conjunctiva, surrounding the eyeball, and (2) the skin. Exposure through the conjunctiva has been subjected to many tests, and it has been found that one of the most certain artificial methods of transmitting Bang's disease to cattle is to deposit 2 or 3 drops of infectious material around the eyeball. In most cases a susceptible, pregnant animal that is exposed in this manner contracts the disease. Even a single drop of such material from an aborted fetus has caused a pregnant cow to become infected and abort. Whether enough infectious material would reach the eyes under natural conditions to cause disease would be very difficult to determine, but it seems reasonable to believe that it could.

Germ Penetrates the Skin in Exposure Experiment

Until recent years, it was generally assumed that disease germs were rarely able to pass through the skin while intact. However, several investigators have proved that this theory does not hold true for all disease germs and that *Br. abortus* can pass through the skin of the guinea pig and cause the disease.

On subjecting cattle to skin exposure, Bureau of Animal Industry investigators proved that the disease can be transmitted to cattle whether the skin is slightly abraded or intact at the time the germs are applied. An experiment was made in which 4 pregnant heifers were exposed to infection by slightly abrading a small area of skin and immediately applying the infectious agent to the injured surface. As a result of this treatment, all of the animals became infected. A similar experiment made with 16 pregnant cattle, in which the infectious agent was similarly applied to the uninjured skin, resulted in 10 of them becoming infected. In both experiments, extreme precautions were taken to eliminate the possibility of the infection entering the animal except in the manner under investigation. It thus appears that *Br. abortus* is not only capable of transmitting Bang's disease to cattle through the slightly injured skin, but can also penetrate the uninjured skin and cause the disease.

The ability of *Br. abortus* to transmit the disease upon coming in contact with the skin, as experimentally shown, suggests certain ways by which this method of exposure would communicate the malady under

natural conditions. Animals frequently abort unexpectedly when stanchioned in stables and before being segregated often grossly contaminate adjacent cattle as well as floors and gutters. Since the uterine fluids of aborting cows are commonly saturated with the *Br. abortus* germs, their contact with the skin of other cows would naturally be expected to furnish severe exposure. Susceptible cows lying on ground contaminated with fresh discharges from aborting cows or standing in barnyard mud or manure contaminated with the germs might readily be exposed to infection through the skin. Cows having slight skin injuries would naturally be in greater danger of contracting the disease than those without injuries.

It appears that the transmission of the disease through the skin is determined to some extent by the numbers of the germs to which the skin areas are exposed and also by their virulence. Milk from a cow infected with *Br. abortus*, in which the germs were known to be present, was repeatedly applied to freshly abraded surfaces of the teats of a susceptible cow, but the animal failed to acquire the disease. Since the milk of cows infected with *Br. abortus* commonly contains relatively few *Br. abortus* germs, its failure to transmit the disease through the slightly injured surfaces of the teats was believed to be due to the relatively small number of germs that were applied. More heavily infected materials, such as uterine discharges from aborting cows, would be likely to transmit abortion disease.

Experimental evidence indicates that afterbirths and uterine fluids from aborting animals, which are usually saturated with the abortion germs, are decidedly more infective for susceptible cattle than milk infected with *Br. abortus*, which usually contains relatively small numbers of the germs.

Precautions to Prevent Human Infection

It is well to remember that *Br. abortus* may cause undulant fever in man and that he, in all probability, can be infected through the skin. It is advisable, therefore, for stockowners and others who care for livestock to take the precaution to wash their hands carefully with soap and water as soon as possible after they have handled aborted fetuses or have come in contact with infected discharges, either from aborting cows or sows. The latter especially are a source of danger because the type of *Br. abortus* that affects swine appears to be more infectious for man than the one that affects cattle.

Bureau of Animal Industry.

BARBERRY Eradication Removes rust-spreading barberry bushes from 13 of the North Central States is proving an effective means of preventing one of the chief causes of poor-quality grain and wide fluctuations from year to year in the yield of small-grain crops. As is the case with many other diseases of farm crops, the amount of damage caused by stem rust during any one season may vary from practically none to complete destruction of the crop, depending (1) upon the amount of inoculum (rust spores) present in the air about the time the grain is heading, and (2) the kind of weather that prevails during the time when the grain is filling.

Not infrequently during the period 1900-1920 in the Great Plains area good crops of wheat, oats, barley, and rye were, in a period of 2 to 3 weeks, partially or completely destroyed by the rapidly spreading, destructive stem-rust disease. Agricultural people viewed with alarm the steadily increasing loss from rust. Unlike other crop hazards, stem rust usually injures the crops when the grain is nearly mature and when moisture and temperature conditions favor a normal or bumper crop.

The seemingly spontaneous manner in which stem rust appears and its disastrous effect upon grain crops resulted in the disease becoming recognized as the most troublesome factor, aside from weather, with which grain growers of the upper Mississippi River Valley had to contend. The stable production of grain of good milling quality was becoming increasingly difficult because of the yield and quality fluctuations resulting from rust damage.

Federal-State Campaign

Since 1918, 13 States—Colorado, Illinois, Indiana, Iowa, Michigan, Minnesota, Montana, Nebraska, North Dakota, Ohio, South Dakota, Wisconsin, and Wyoming—and many independent organizations of farmers and business people have cooperated with the United States Department of Agriculture in an effort to remove from the North Central States this local early-spring source of stem-rust spores. During this time nearly 20 million rust-spreading barberry bushes have been destroyed. The following figures indicate that progress in eradication has been accompanied by a steadily decreasing amount of rust: During the period 1916-21 the average annual loss to wheat in these States was 51 million bushels; for the period 1922-27 the average annual loss was 17 million bushels; and for the period 1928-33 the average annual loss had decreased to approximately 4 million bushels.

Although many barberry bushes remain in out-of-the-way places within these States, a great many bushes so located as to be a continuous rust menace to small-grain crops have been destroyed. With the opportunity for further insuring grain growers against the rust hazard and stabilizing the production of grain crops, the Public Works Administration in 1933 authorized the expenditure of N.R.A. funds to clean up many areas where barberry bushes were known to exist but where limited funds had prevented previous organized eradication efforts. Several years of progress in combating the stem-rust hazard furnishes an abundance of evidence that complete eradication of the rust-spreading barberry in the upper Mississippi River Valley will do much to prevent future widespread destructive epidemics of the disease.

W. L. POPHAM, *Bureau of Plant Industry.*

BEEF Grade is Affected
Chiefly by Feeder Grade
and the Feed-Lot Gain

Studies conducted cooperatively by the Department and many State agricultural experiment stations in connection with the Nation-wide project, cooperative meat investigations, have thrown new light on the effects of the grade of feeder cattle, their gains in the feed lot, and other factors upon the grade of beef produced by such cattle. In certain respects this new information makes possible the control and measurement of these effects on a very definite basis.

Results with Steer Calves

In these studies data have been obtained on a large number of cattle of different ages, weights, and sexes. One group of 441 feeder steer calves, weighing 400 pounds and up when they were started on the finishing ration, has furnished results of particular interest.

The calves were graded as feeders, again at the close of the finishing period as slaughter cattle, and finally as dressed carcasses. They were graded individually according to a standard method taking conformation, finish, and quality into account. The work was done by a committee of three trained men. The feeder-cattle grades used were Fancy, Choice, Good, Medium, Common, and Inferior; the slaughter-cattle and carcass grades were Prime, Choice, Good, Medium, Common, Cutter, and Low Cutter.

The 441 steer calves graded as follows: 51 Fancy, 261 Choice, 106 Good, and 23 Medium. The average initial weights were about 500 pounds. The feed-lot gains made by the steers were studied in connection not only with the feeder grade but also with the resulting slaughter-cattle grade and the carcass grade of each animal. Though it is possible to determine the different grades of carcasses in the live slaughter animal with a high degree of accuracy, carcass grade is naturally a more direct measure of the quality of beef, and there is evidence that normally the carcass grade is judged with greater accuracy than the slaughter-cattle grade.

In the group of steers studied the animals that graded the lowest as feeders required the least gain to produce a corresponding carcass grade. The Medium-grade feeders produced Medium carcasses after gaining approximately 185 pounds. The Good calves produced Good carcasses, and the Choice calves Choice carcasses after gaining approximately 270 and 380 pounds, respectively. The Fancy feeders, though gaining a maximum of 471 pounds, did not produce Prime-grade carcasses.

A study was made also of the different quantities of gain required by the various grades of feeders to produce a particular grade of carcass. It was necessary for Good steers to make gains of about 460 pounds in order to produce Choice-grade carcasses. The Choice steers, however, produced Choice carcasses after making gains of about 380 pounds, while Fancy feeder calves produced Choice carcasses with 310 pounds of gain. Thus the higher the grade of feeder the less increase in weight is needed to produce a carcass of a given grade.

Another important finding of this investigation was that at any given gain the spread in average carcass grades tended to be less than the spread in the grades of the cattle as feeders. For instance, there is a difference of three grades between Medium and Fancy feeder cattle. When the cattle of these grades gained 325 pounds the range of differences in the resulting carcasses was only 1.2 grades. As the quantity of gain increased the difference in carcass grade between the Good and Choice feeders tended to become less. In fact, after about 400 pounds' gain the carcasses of Good steers graded almost as high as those of the Choice cattle. The steers graded as Fancy were the only ones showing indications of ability to produce carcasses of highest grade.

Importance of Finish in Carcass Grades

The results of this investigation showed also that all grades of feeder cattle as a rule would produce relatively low-grading carcasses if slaughtered early in the fattening period. This is because of lack of

finish, which is one of the most important factors of carcass grade. The results indicated that when steers made low feed-lot gains, the lower grade feeders lost less in carcass grade than the higher grading feeders. For example, if a typical Medium feeder steer is slaughtered after gaining 200 pounds in the feed lot, the carcass may be expected to grade about 0.4 of a grade lower than the feeder. Under similar conditions the carcass of a Good steer calf would decline about 0.9 of a grade, and that of a Choice calf about 1.4 grades. Consequently, the higher grading feeders should be fed for at least moderate gains if advantage is to be taken of their potential ability to produce high-grade beef.

An analysis of similar data obtained in the feeding and slaughtering of more than 2,000 cattle varying widely in age, weight, grade, and length of fattening period, has shown that feeder grade and total gain in the feed lot had approximately equal influences on the grade of the carcasses.

Further analysis of steer-calf data has shown that variation in initial weights within a feeder grade influences the grade of carcass to some extent though not so much as the influence of grade and of feed-lot gain. In general, the heavier the animal when placed on feed the higher was the grade of carcass when gains were equal. A rapid gain appeared to be favorable to a higher grading carcass, though this factor also was a comparatively minor one.

In the results outlined, cattlemen have a basis for conducting feeding operations in a manner that enables them to control to a high degree the grade of slaughter animals and their carcasses. The grade of feeder cattle and the quantity of gain are major influences. The weight of feeders and the rate of gain, though less important, deserve consideration and attention. By taking all these influences into account cattlemen may judge with reasonable accuracy the results to expect under a given set of conditions.

L. B. BURK, *Bureau of Agricultural Economics*.

BIRD Species Not Menaced by Local Control Campaigns Rightfully alert to dangers threatening birds, nature lovers have been alarmed by certain reports on the results of control measures. Some of these reports have been misleading, however. In the first place some bird control is necessary and will be carried on regardless of sentiment or regulations. Recognition of the right of defense against serious depredations by any animals, including birds, is unavoidable. Individual defense against serious depredations is always justifiable, and local cooperative efforts may be. The larger the scale of cooperation, however, the more the public interest is involved and the more debatable the procedure. No large-scale operations for bird control are planned by the Bureau of Biological Survey, and no general campaigns have ever been approved. Hence, so far as Federal participation is concerned, bird lovers need not be disturbed over dangers of highly organized schemes of bird control.

The necessity for some control, however, is generally admitted. Losses from birds exist in every degree, from those of trifling consequence—which although of almost universal occurrence are equally

widely condoned—to those that can be estimated only in very large sums, or are even so serious as to compel the abandonment of industries in areas where, aside from the presence of crop pests, conditions may be particularly suited to them. Many examples of serious damage are on record and could be cited, but the present purpose is to discuss the character and the effects of control methods.

Preventive and Aggressive Measures

All of us prefer measures of the preventive type that do not involve death to the birds, but such methods are not always feasible. As a rule frightening devices (scarecrows and the like) are effective only when novel; familiarity with them soon breeds contempt. Other preventive methods that have been used include tarring seed grain, planting it too deeply to be readily dug out by birds, covering a few trees or small berry patches with bird-excluding netting, choosing early or late-maturing varieties with relation to their susceptibility to bird damage, harvesting early, or otherwise varying farm practices to minimize bird depredations.

Often none of these devices avail, and aggressive measures are in demand. "Bird-minding", or the patrolling of areas and shooting at the birds or otherwise frightening them, usually with only a little actual killing, has long been practiced, but is not always effective. Shooting at birds that destroy small fruits involves perhaps the next greater degree of control. Some species, as robins, are unwary and, to be controlled locally, must be practically shot out; others, as starlings, are wary and soon avoid a dangerous area. Shooting, however, is expensive, both in labor and materials. Trapping has been little employed, except against birds of prey and English sparrows, and its possibilities are little known in connection with destructive birds in general. It is clear, however, that on large areas the methods thus far mentioned are so impracticable or prohibitively expensive that they will not be used. Use of poison baits is the next resort, and this method has the advantages of relative cheapness and greater possibilities of economical application to large areas.

Control Sometimes Impracticable

Often control measures are not economical and hence are not attempted. There may be other circumstances also that render bird control impracticable. In illustration it may be recorded that though investigations of crow depredations in Oklahoma confirmed reports of vast numbers of crows and of serious damage done by them, they revealed so great an abundance of food in unharvested crops, shocked cereals, and pastured grainfields, that all parties concerned agreed that an effective control campaign was impossible and that recourse must be had to alterations in farm practice.

Bird control, it must be concluded, is a self-limiting activity. On a small scale it is unnecessary; on a large scale it is impracticable. In the intermediate categories, economics will rule in the long run, and in a large proportion of cases, so far as can now be foreseen, control will be prohibitively expensive. Furthermore, bird control does not ordinarily affect the species that are favorites with bird lovers. No control is needed for wrens or bluebirds, chickadees or warblers, swallows or phoebes. Most of the familiar species that the ornithophile has in

mind when he thinks of birds are never involved in control operations. The only notable exception is the robin, and the universal abundance of the species shows that it has not been injured by control operations.

Few Species Require Extensive Control

In its entire history the Biological Survey has found it desirable to publish instructions for control of only certain hawks and owls, crows, magpies, pinyon jays, starlings, blackbirds, and English sparrows, and the whole list of birds involved in control operations anywhere in the United States is scarcely as long again. The general policy of the Bureau is to hold bird-control work to a minimum. In each case study of the situation in the field, development preferably of preventive methods, or, if necessary and possible, the setting up of aggressive control measures, with subsequent dissemination of information on the results obtained, are held to fulfill the Bureau's obligations. Large-scale control campaigns and far-reaching extension projects are not contemplated. The underlying principle recognized is that economic problems involving bird life are characteristically local and that means of adjusting them must vary with, and should be confined to, the localities where needed. In making adjustments of wild-life relationships for economic reasons, we should do whatever is required, but no more.

The charges of wholesale destruction of birds in control campaigns in most cases are entirely unfounded, and there are practically no instances of indiscriminate slaughter of birds of all kinds.

A little reflection should lead to the conclusion that there is small cause for uneasiness as to the results of bird-control operations in general. This is true not only because of the various limiting factors already discussed, but further because bird control in the last analysis almost always is strictly a local action against an abundant and usually also a widespread species. It is the very factor of overabundance of birds that brings on damage and the ensuing efforts at control. The insignificant effect of these efforts upon the total bird population is evident on every hand.

The foregoing applies to the general run of control measures based on economic reasons, directed against highly vegetarian species of birds. It does not apply to bounty systems, side hunts, and other organized onslaughts against the larger predatory birds, none of which has ever had the approval of the Bureau of Biological Survey. These constitute warfare, not control, and because of the long-continued intensity of such campaigns and the smaller number of the birds against which they have been directed, the results in some cases have been disastrous.

Existence of Widespread Species Seldom Threatened

No such campaigns, however, have been waged against any of the species of either seasonal or almost year-round vegetarian-feeding habits. Consider for instance the linnet, or house finch, which was the most destructive bird in California in the seventies and eighties, when horticulture was just getting established there. The Pacific Rural Press of those years teems with references to the destructiveness of this bird. It was shot, poisoned, destroyed in every way the growers could think of, and it has been fought ever since. Today, after more than 60 years of such treatment, it is still the most destructive bird of

the State. What is more, the aggressive actions against it so far as known have not depleted any associated species.

The crow in the East has been fought for more than 200 years. Since colonial times it has been outlawed, and shot and poisoned at every opportunity. Nevertheless it has maintained its numbers and steadily spread westward. It has accompanied its enemy man, persisted in spite of him, and increased with his increase. Similarly in the Old World, rooks and house sparrows are still abundant, though persecuted for ages.

The story of the bobolink, reedbird, or ricebird, most nearly epitomizes "control" of abundant species of largely vegetarian proclivities. The rice industry that developed on the South Atlantic coast was located directly in the migration path of bobolinks, through which the birds funnelled from a range almost continental in width. In myriads they took enthusiastically to the rice, and for more than a hundred years they were fought unceasingly in every imaginable way. Now the rice industry of that section has been ended by western competition, but the birds remain. The bobolinks traverse their accustomed migration path, as did their ancestors for ages before them, serenely unaware that there ever was such a thing as bird control.

Efforts at bird control are exceptional indeed if they succeed well enough to justify their name; and seldom do they develop into threats against the existence of species. So long as suitable range exists for a widely distributed bird, local action against it is not to be feared, and bird control practically always means local action against an abundant species. If suitable range ceases to exist, because of human occupation or the destruction of necessary environmental factors, nothing can save the species affected. Only to this trouble, largely an incurable one, and not to bird control, can be properly traced certain of the regrettable cases of impairment of our avifauna.

W. L. McATEE, *Bureau of Biological Survey.*

BLISTER Rust Control Program Gives High Degree of Protection

Three particularly cogent reasons of an economic nature have been advanced in justification of the program to protect western white pine from white pine blister rust. The destruction of these pines would (1) destroy community values in the region, (2) destroy the timber value upon which important regional industries are based, and (3) very possibly destroy the lumber values of all soft pines for a temporary period because of the rapid exploitation of western white pine as it becomes immediately threatened by the rust. The third of these possibilities is a very real one and for the period of its duration would seriously dislocate the lumber market and values of the entire country as well as of the particular region. The progress of the blister rust control program in the "Inland Empire" region, technically directed by the United States Department of Agriculture and jointly financed by Federal, State, and private funds, has now reached a scale of performance and a degree of efficiency that largely dissipate this threat. Owners of western white pine timber who might possibly be led into unduly rapid exploitation of their timber resources through fear of loss occasioned

by the rust are now able to secure from the Department information that will assure them that no such action is necessary.

Since the inception of the blister rust control program in the "Inland Empire" approximately 451,000 acres of white pine bearing lands have been cleared of wild currant and gooseberry plants. These plants are the alternate hosts of the disease, and without their presence the rust cannot spread from pine to pine. Of this total area, 231,000 acres had been worked over prior to 1933. During 1933 approximately 165,000 acres were worked over through the operation of the Civilian Conservation Corps, while the work on the remaining 55,000 acres was financed from regular appropriations of the Department and from allotments from the Federal Public Works program. The projected application of Public Works funds to this project during 1934 should result in the protection of several hundred thousand additional acres of white pine land. By the end of the summer of 1934 it is expected that approximately three fourths of a million acres of white pine land out of a total of $2\frac{1}{2}$ to 3 million acres will have been worked over for the first time.

High Degree of Protection Obtained

Field studies in areas in which the disease occurs and from which these wild currant and gooseberry bushes have been removed show that this process results in a satisfactorily high degree of protection to the pine. In numerous cases further spread of the disease to healthy pines has been entirely stopped by the eradication of these alternate hosts.

The combination of continued progress in the control program and technical assurance that the work is resulting in pine protection will permit owners of white pine timber to continue their lumbering operations at a normal rate without fear of sudden loss from blister rust. A long-range program of white pine silviculture on the areas naturally suited to it, combined with a similar long-range program for the control of its chief enemy, the blister rust, is at this time not only to be desired and recommended but also appears to be absolutely imperative.

STEPHEN N. WYCKOFF, *Bureau of Plant Industry.*

BUTTER Quality Higher
In Tennessee Following
Educational Campaign

A much-desired improvement in the quality of Tennessee creamery butter has resulted from the educational work conducted during the last 9 years by the Bureau of Dairy Industry and the Agricultural Extension Service of the University of Tennessee.

Just before this "efficiency and quality campaign" was started, in 1924, a survey of existing conditions revealed the fact that the herds were small (4 to 7 cows) and that they were in the hands of inexperienced dairymen. Dairy farms were few and far between, and there were few if any facilities on the farms for the care of milk and cream. The temperature of the water supply averaged about 60° F.

Creameries were inadequately equipped and in a majority of cases managed by operators with no technical training and little if any practical experience. The butter manufactured was of very poor quality, 90 percent of it grading about 87 or 88. Samples of butter collected

from the creameries of the State showed an average fat content of 82.62 percent, whereas the Federal standard required only 80 percent fat. Allowing a standard of 80.5 percent fat as a margin of safety, 82.62 percent fat represents a loss to the creameries of 2.12 pounds of fat or 2.61 pounds of butter for each 100 pounds of butter manufactured. Valuing this butter at 43 cents per pound, this lack of manufacturing efficiency cost the creameries of the State \$128,650 during 1923. Processing and manufacturing methods were found to be on about the same low levels as that of composition control.

With the beginning of the campaign in May 1924, a uniform standard of cream grading was inaugurated in one of the leading cooperative creameries in the State, the cream all being paid for on the basis of the following grades, with a differential in price of 3 cents per pound of fat between each grade.

Premium grade—clean in flavor and not exceeding 0.20 percent acidity.

No. 1 grade—clean in flavor and between 0.21 and 0.40 percent acidity.

No. 2 grade—unclean in flavor or/and exceeding 0.40 percent acidity.

Onion grade—cream having onion flavor.

When the grading work was first started in this cooperative creamery less than 10 percent of the cream received was of Premium grade, and not more than 25 percent was No. 1 grade.

Meetings of cream producers were called, and methods of producing and caring for cream on the farms were discussed, and for a short period a field man from the Bureau of Dairy Industry visited the dairy farms and assisted cream producers in preparing cooling facilities and instructed them in the proper care of cream.

Program Immediately Successful

Within a few months this creamery was marketing a good percentage of its butter at from 3 to 5 cents per pound above prices it would have received if the quality-improvement campaign had not been started. The increased price received for butter was passed on to the producers in the price paid for butterfat, and this creamery led the State in prices paid for fat for a number of years. The success of the quality improvement in this creamery attracted the attention of creameries and cream producers in other sections, and similar attempts to improve the quality were made in every section of the State. The response by creamery operators and cream producers was very fine and proved profitable to the producers.

During 1932 more than 90 percent of the cream received by local creameries in Tennessee was graded and purchased on a basis of acidity, flavor, and odor. In creameries using cream purchased through cream-buying stations the method of grading on flavor and odor was hardly practical, and for this group a method of classifying and paying for cream on a basis of age had been adopted, the age classifications being cream 2 days old, 4 days old, and over 4 days old. Approximately 99 percent of the cream purchased in the State was graded and paid for in accordance with one of these two methods, there being only 2 or 3 very small creameries that did not grade and pay on a quality basis.

Cream producers in general cooperated liberally in the quality-improvement work. A few were skeptical, however, and very few appreciated the importance of thorough sterilization of equipment and effective cooling and frequent delivery of cream if high-grade butter

was to be produced. The Bureau specialist spent many days on the cream-receiving platforms, explaining in detail methods of producing and caring for cream on the farm. The Bureau specialist also inaugurated a project in which home demonstration agents conducted demonstrations covering the care of milk and cream and the manufacture of butter, cheese, and cottage cheese on the farm. More than 8,000 women club members received instructions in the care of milk and cream through these meetings.

Butter Higher in Quality

Five local creameries that have cooperated in the quality-improvement work and adhered more closely to the uniform standard of grading, received, in 1932, a total of 2,381,431 pounds of butterfat, from which 2,949,213 pounds of butter was manufactured. This butter, scoring 89 and 90, was at least 2 points higher than the butter made previous to the campaign, which scored 87 to 88. The spread in price on the Chicago market between grades of butter that scored 88 and 90 averaged 1.16 cents a pound for 1932. This increased price of 1.16 cents per pound on the 2,949,213 pounds of butter manufactured in 1932 indicates an added income for the year of \$34,210.87 to these five creameries as a result of improving the quality of their butter.

The percentage of each grade and the average price paid for fat by the five creameries in 1932 were as follows:

Premium grade, 18.363 percent, 21.637 cents per pound.
No. 1 grade, 76.262 percent, 18.100 cents per pound.
No. 2 grade, 4.802 percent, 14.376 cents per pound.
Onion grade, 0.573 percent, 12.312 cents per pound.

As a part of the quality-improvement campaign monthly educational butter scorings were held at local creameries over the State, where the operators of various creameries gathered for discussion of grading and manufacturing problems. Each operator sent or brought samples of his butter to these meetings. The samples were examined and graded by the Bureau specialist, defects were discussed, and methods of avoiding such defects were explained to the operators. The composition of each sample was determined, and the methods of analysis were demonstrated, with the result that each creamery was provided with equipment so that the operators themselves could check the composition of each churning. Following these meetings, the Bureau specialist visited the individual creameries, assisted in cream grading, and demonstrated the methods of quality improvement and composition control in the manufacturing process.

As a result of these monthly educational scorings and the individual demonstrations and short courses held at the University of Tennessee, which a large number of creamery operators were induced to attend, the creamery operators have become very efficient in their work. The average fat content of butter now more nearly conforms to the Federal standard, and they are able to manufacture a higher grade of butter from the same quality of cream.

Results at Butter-Scoring Contests

A number of Tennessee creamery operators exhibited samples of butter at butter-scoring contests in 1932. While these samples do not represent the average quality of butter manufactured, they do reflect the general improvement in quality, and they also show the skill of the

operator in selecting high-quality cream and his ability to make butter of fancy quality. At the Midsouth Fair at Memphis in 1932, 11 entries from Tennessee received an average score of 92.07 points, while 29 entries from 10 other Southern States received an average score of 89.94 points.

In the Tennessee master buttermaker's contest the man whose butter receives the highest average score in 1 southern and 4 national contests is designated the master buttermaker for that year. The highest average score of the seven contestants in 1932 was 93.3 and the lowest 92.38.

The excellent keeping quality of Tennessee butter and the buttermaker's ability to select cream of excellent quality, and his manufacturing efficiency is reflected in the seven samples entered by Tennessee buttermakers in the master buttermaker's contest at a national butter contest at Mason City, Iowa, in 1932. These entries received an average score of 92.69 points when fresh and 93 points after 3 months in storage.

In this same cold-storage contest one of the old dairy producing States had 154 entries, which received an average score of 92.88 when fresh and 92.77 after 3 months in storage. Another had 101 entries with an average score of 92.77 when fresh and 92.51 after storage. A third had 44 entries with an average score of 93.14 when fresh and 92.90 after storage.

Tennessee butter, a large percentage of it grading 90 to 92, is today stimulating an increased consumption of butter in the Southern States and is replacing much of the very low-grade butter that was formerly dumped on this market, and in the eastern market a trade has been developed that demands Tennessee butter, affording a very satisfactory market.

As a result of this campaign through the splendid improvement in manufacturing efficiency by creamery operators and their earnest efforts in cooperation with cream producers of the State in quality improvement, Tennessee received nearly \$250,000 additional income in 1932 for butterfat marketed through its creameries.

CASEIN Manufacturing By New Methods Cuts Costs, Improves Product

The manufacture of commercial casein is of increasing importance to the dairy industry because of the great quantities of skim milk available for processing daily in dairy-products plants, particularly during the period of greatest milk production. Prior to 1931 more casein was imported than was produced in the United States, but since the increase in the tariff rate in June 1931 from 2½ cents a pound to 5½ cents, casein imports have been small. However, conditions may develop which will again favor the importation of casein.

There are products which have been used as substitutes for casein, and others may be developed. It is known, for instance, that the soybean contains protein material which resembles casein and that, like casein, this protein has been used in the manufacture of glue and plastics. In fact, soybean milk is similar in many respects to cow's milk. Starch has also been used as a substitute for casein and market conditions may develop which will cause it to displace casein

to a considerable extent. It, therefore, behooves the American manufacturer to make casein which will not be at a disadvantage, from the standpoint of its quality or cost of production, in competition with imported casein or with other products.

The Bureau of Dairy Industry has interested itself in the many problems of the casein-manufacturing industry, and in a number of instances has helped to bring about the development of new or improved equipment, the advantages of which will be apparent from a comparison of the new mechanical or continuous processes with the so-called "old hand" or "batch methods."

In the old hand or batch methods skim milk in rectangular vats is warmed, during agitation by the operator, to the desired setting temperature, and a culture of lactic-acid-producing bacteria is added. The properties of this culture or starter may vary greatly, but in any event its primary purpose is the same, namely, to bring about fermentation with subsequent coagulation of the skim milk. The coagulum is broken up and the resulting pieces of curd, following heating while being stirred with a rake, shrink and settle out, and are separated from the whey by draining the whey from the vat. Water is then added to the curd, the mixture is stirred, the wash water is drained away, and the curd shoveled into a suitable cloth in which it is pressed with the aid of a screw-type press. Pressure is usually applied overnight. Following the removal of the curd from the press, it is shredded and spread on trays. The trays are placed on trucks, which are then wheeled into tunnels where the curd is dried by means of a current of hot air. This part of the process usually requires 7 hours. On removal from the drier, the casein may be ground and bagged, or it may be shipped unground.

It will be seen from the foregoing outline of the customary manufacturing process that much manual labor is required and the process is not completed until the afternoon of the day after the skim milk is available.

New Methods for Reducing Costs

A few of the largest and more progressive casein manufacturers have developed improved methods whereby operating costs have been reduced, while at the same time the product has been improved. Facilities are now in use which make it possible to process large quantities of skim milk with the services of only two men. The isolating, washing, and pressing steps are continuous and automatic and require but a few minutes. The pressed curd is shredded and passes mechanically to a drier, which may be either the continuous revolving drum or the sectional conveyor type whereby the curd is dried in from 30 to 60 minutes. It is believed that the completion of the casein manufacturing process in a short time is desirable because it tends to result in a superior product.

The development of methods which will contribute further to the production of commercial casein at less cost and in a more uniform manner is possible and desirable. The cost of this equipment should be such that the average casein manufacturer will buy it.

R. W. BELL, Bureau of Dairy Industry

CHANCE Tree Hybrids of Fast Growth Inspire Timber-Tree Breeding Along the north side of Lafayette Square, in the city of Washington, near its Madison Place end is a row of five majestic elm trees, much taller than any other trees in the square. These elms have reached their present dimensions notwithstanding their situation between the sidewalk and the street, with a 75-foot sheet of concrete to the north of them and a 20-foot strip to the south. These trees have a strange history. They were propagated from the English elm, a tree that has been grown for centuries in England, and which there sometimes reaches the imposing height of 140 feet and the diameter of 8 feet. In the opinion of the eminent authority on British trees, Augustine Henry, the English elm is an accidental hybrid between two species of elm native in England, the Scotch elm and the smooth-leaf elm, both of which it greatly exceeds in size. Its original vigor is maintained through propagation by rooted suckers, not by seeds. The location of the original tree from which the Lafayette Square specimens were propagated is unknown.

In Great Britain there is another amazing tree known as the cricket-bat willow. It grows to a height of 100 feet and a diameter of 5 feet. From the wood of this willow the English make cricket bats, just as we in the United States make baseball bats out of white ash. This willow is propagated by cuttings, and only the female trees are known. All the present trees undoubtedly were propagated from a single original plant. Without question Elwes and Henry are correct in their conclusion that this tree is a natural accidental hybrid. It grows faster than any other English willow.

In California the Persian walnut, sometimes called the English walnut, does not thrive when grown on its own roots. It has therefore become the practice to graft it on the Hinds walnut, a species native to California and adapted to both its soil and its climate. Occasionally one of the grafts fail, and a sprout from the stock grows up and becomes a tree of the native species, surrounded by trees of Persian walnut. In the pollination of walnut flowers, the pollen is carried by the wind. By accident the wind sometimes cross-pollinates one of these native walnuts with the Persian walnut. A nut resulting from one of these accidental pollinations does not differ in appearance from other nuts on the same tree; but when such a nut germinates and grows into a sapling, it not only shows by its foliage that it is a hybrid, but it possesses astonishing vigor, far greater than that of either parent. It has been recorded that one of these so-called "Paradox hybrids" at Yuba City, Calif., was 99 feet high and 5 feet in diameter when it was credited with an age of about 40 years.

On Rowe Farm, Charles City County, Va., on the north bank of the James River, midway between Richmond and Williamsburg, grew an immense walnut tree, which in 1914 was almost 10 feet in diameter at 4 feet from the ground. It was identified by botanists as a hybrid between the black walnut, which is native there, and the Persian walnut, which had been introduced from Europe by the early colonists. Presumably the tree grew from a nut of a Persian walnut tree which had been accidentally pollinated by a black walnut. In 1928 the hybrid tree was cut for its wood. Even its roots were dug and sold. The especially regrettable thing about it is that, so far as is known, no propagation material of this tree was saved.

At Dunkeld, Perthshire, Scotland, were planted a few trees of the Japanese larch, *Larix leptolepis*, grown from seeds that were sown in 1885. Near them are many trees of European larch, *L. europaea*. From seeds produced on these Japanese larches as early as 1904, and clearly the result of accidental wind-pollination between the two species, were developed trees that grew very much faster than either parent. One lot of these Dunkeld hybrid larches averaged 29 feet in height at the age of only 8 years, an astonishing vigor of growth in a larch.

The lesson conveyed by these accidents of nature is that if we take up the breeding of timber trees and pursue it intelligently we shall be able to do on a large scale what nature has done only rarely. Systematic experiments in the cross-pollination of timber-tree species may be expected to yield many hybrids that grow much faster than either parent. When such results have been demonstrated by experiment, and a forest planting is to be made, the advantage of using fast-growing hybrids is manifest. If, for example, a hybrid between two of our best lumber species of the white pine group will produce trees of full timber size in 50 years instead of the customary 80 years, the owners can cut their trees and liquidate their investment at the end of 50 years, and at the end of 80 years can have a second stand of timber three fifths grown.

Tree-Breeding Experiments Few

Intentional experiments in the improvement of timber trees by breeding are few. Stout, at the New York Botanical Garden, has bred poplars that in one summer have made 8-foot sprouts from the stumps of 1-year-old rooted cuttings. At the Institute of Forest Genetics, Placerville, Calif., Austin and Wrighter are carrying on experiments in tree breeding that give great promise of valuable results.

Although the production of tree hybrids should be begun with small-scale experiments, their production on a large scale undoubtedly will be found to be feasible. Hand-pollination on a small scale can be followed by tent-pollination, especially if it is found that the individual tree is sterile to its own pollen, as is true of many other plants. And experiments may show that valuable hybrids may be produced at small expense by the simple expedient of planting isolated trees of one species in plantations of another species.

One of the members of the National Arboretum staff has bred the wild blueberry from the size of birdshot or buckshot to a diameter of more than an inch, an accomplishment which at the beginning would have been unbelievable. Another member of the Arboretum staff, in a series of experiments, crossed the swamp magnolia with the southern magnolia. The hybrids have grown much faster than seedlings of either parent. A computation made in the spring of 1933 showed that the hybrids had produced $2\frac{1}{2}$ times as much wood as one parent and 8 times as much as the other.

It is well known that successful plant breeding requires intelligence and skill, and it is believed that the requisite skill and intelligence are available for the breeding of timber trees.

The time has come when the interest of forest development in the United States requires systematic and extensive experiments in the production of faster growing timber trees. It is an almost untouched field

of research and accomplishment. The necessary experiments can be begun as soon as the National Arboretum is put on an operating basis.

FREDERICK V. COVILLE,
Acting Director, National Arboretum.

CHEMICALLY Treated Bands Effectively Aid Codling-Moth Control

The successful culture of the apple in the United States is dependent upon the surmounting of many obstacles, one of the most serious of which is injury by the codling moth or apple worm. This insect, in its larval or worm stage, eats its way into the apple and consumes much of the flesh, rendering the fruit practically worthless for commercial purposes.

As early as a century ago fruit growers discovered that the codling moth could be partly controlled by trapping the larvae in bands applied to the trunks of apple trees; prior to the use of poisonous sprays, banding was the only practical means of reducing the infestation. The bands were usually made of straw or rags.

The codling moth lays its eggs on the leaves and fruit during the growing season. After hatching, the larvae seek the fruit for feeding, and when mature they usually spin their cocoons under the loose bark of the trunk and the larger limbs. The fruit grower takes advantage of this habit by scraping off the loose bark and applying a band which serves as an attractive place for the spinning of these cocoons.

By using suitable banding material and scraping the trees well, it is possible to capture from 40 to 50 percent of the worms that have fed within the fruit. In order to prevent the emergence of moths, however, it has been necessary to "hand-work" the bands at intervals of from 1 to 2 weeks during the summer. This operation involved the removal of the bands from each tree and the mechanical killing of the worms that had cocooned in contact with them. Cloth bands were sometimes run through a clothes wringer, and those larvae that remained attached to the trunk were crushed with various types of blunt instruments.

The destruction of codling-moth worms by hand is still practiced by many orchardists, especially in regions favorable to the codling moth, as a supplement to control by spraying.

Banding would undoubtedly have been more widely practiced in the past had it not required so much hand labor. The chemically treated band, a recent invention of the Bureau of Entomology, eliminates much of the labor involved in orchard banding, as it automatically kills the worms that spin cocoons in contact with it.

In order to make such a self-working band practicable, the chemicals to be used had to meet certain requirements. They had to kill the worms by contact and yet be noninjurious to the tree; they had to be cheap, readily applied, insoluble in water, and adhesive to resist washing by rain; they had, likewise, to be sufficiently nonvolatile to prevent too-rapid loss by evaporation; furthermore, it was necessary that they be nonrepellent to the larvae.

Effective Chemicals Found for Banding

After considerable experimentation it was found that a mixture of beta-naphthol (technical grade) and lubricating oil (red engine type) fulfilled all these requirements, and a band treated with these materials

is now available. The band is tacked to the tree trunk early in the spring, and is effective without further attention for the entire season.

The bands are prepared by coating strips of single-face corrugated paper with beta-naphthol and oil. Strips of burlap or cheesecloth were used in the earliest experimentation with the self-working bands, but it was found that in such bands the chemicals caused injury to the tree. The corrugated-paper bands provide less contact with the tree trunk and afford greater opportunity for air circulation than cloth bands, and are safe to use on bearing trees old enough to have developed rough bark. The corrugated paper is now cut by the manufacturer into rolls 250 feet long and of any desired width, usually 2 to 4 inches. Thus, by dipping a roll of corrugated paper in either a hot solution or a cold especially prepared mixture of beta-naphthol and oil, 250 feet of treated band material can be quickly made.

Orchardists are now making bands at a cost, exclusive of labor, not exceeding 1 cent per linear foot for a 2-inch width. These bands are also being offered commercially at a somewhat higher price.

Chemically treated bands are now widely used by fruit growers, and it is expected that the practice will be considerably extended from year to year. A recent survey has shown that one third of the bearing orchards in one of the fruit districts of the Pacific Northwest are now equipped with treated bands.

FIGURE 32.—Demonstration of method of making chemically treated bands on a commercial fruit farm.

Bureau of Entomology.

CITRUS Fruit Resists Stem-End Rot Better By Newer Borax Treatment

Stem-end rot is one of the major forms of decay of citrus fruits produced in humid areas, oranges being especially susceptible. It results from infections that occur while the fruit is still on the tree. The sources of this infection are in dead twigs, from which the rot-producing organisms are spread by dew drip and rain spatter.

Although this rot can be lessened by spraying and pruning, there are no economical control measures that can be employed while the fruit is on the tree. The rate of advance of the fungi into the fruit depends upon the maturity of the fruit and other conditions. During the early part of the shipping season the fruit is less subject to rapid development of stem-end rot than later, but dead-ripe fruit rots very rapidly.

Ordinarily there are no visible signs of infection at the usual harvest time; hence even by the most careful inspection during the packing operations it is impossible to cull out all of the infected fruits.

After harvest, spoilage from stem-end rot may be accelerated greatly by unfavorable coloring-room conditions such as insufficient ventilation, inadequate circulation, or too much coloring gas, as well as by allowing too much time to elapse between harvesting and getting the fruit under refrigeration.

The most effective method of reducing stem-end rot is to dip the fruit in 8-percent borax solution as soon as practicable after harvest. In recent investigations of the United States Department of Agriculture the borax treatment was found to be much more effective when given as the fruit arrives at the packing house than when delayed until after the usual coloring treatment, as is the customary commercial practice.

Heating the Borax Bath

During cool weather it is difficult to keep the proper concentration of borax in solution, owing to its relatively low solubility. In order to be certain that all of the borax is in solution, the temperature of the bath should be held well above the saturation temperature for the desired concentration. This requires arrangements for heating the borax bath. Experience has shown that an 8-percent solution used at a temperature of 100° to 110° F. gives most satisfactory results. It has also been shown that for best results the temperature of the rinsing of the fruit should not be lower than 90° when the fruit is treated, since otherwise an inadequate amount of borax will adhere to the fruit. This may make it necessary to warm the fruit before treating it in cold weather.

This modification of the borax treatment was put into commercial usage during the season of 1931-32, and hundreds of carloads of fruit have since been treated, with satisfactory results.

The maturity of the fruit at the time of treatment is a factor in the effectiveness of the borax bath in controlling stem-end rot. With the fruit commonly shipped to market, there is usually from 3 to 5 times as much decay in the untreated fruit as in that receiving the borax treatment on the day it is picked. However, the same treatment is not markedly effective in checking decay in dead-ripe oranges.

In very warm weather the borax treatment alone should not be depended upon to reduce stem-end rot in fruit that is especially liable to this decay. Such fruit should also be packed as quickly as possible and placed in precoolers or iced cars and sent to market without delay. The merchant, and the consumer as well, can reduce losses from stem-end decay by holding citrus fruits at temperatures below 50° F. This low temperature not only retards decay but prolongs that fresh-from-the-tree flavor.

JOHN R. WINSTON, *Bureau of Plant Industry.*

CORN-HOG Production-Control Program Follows Emergency Purchases

Production of hogs as well as the production of livestock and livestock products has been maintained at predepression levels during the last 4 years. This production has been maintained in the face of circumstances that ordinarily would be expected to result in a sharp curtailment of production. Three of the last five corn crops have been among the shortest in a quarter century. The market for American hog products abroad has been greatly reduced by the decline in the purchasing power of foreign consumers and the erection of higher and higher trade

barriers between nations. Consumer purchasing power in this country has declined more drastically than in any other important nation, and farm prices of livestock have been at extremely low levels.

Need for Collective Control of Production

Farmers acting as individuals cannot control output in order to increase prices for the products they have to sell. Agriculture is made up of several million independent producers, each competing with the other. The production of each farmer is such a small part of the total that a decrease on any one farm or on several farms has no effect on the price of the product. Furthermore, the farmer cannot discharge his "labor" in order to reduce expenses and curtail production, because on most farms the labor supply is made up of the farmer and his family. In fact, this labor supply has been increased on many farms by the return of relatives who have lost their jobs in the city.

Production of industrial goods, of articles farmers buy, on the other hand, has been sharply decreased since 1929, and only during the last year or so has there been any indication of recovery. Industrial producers have reduced both the number employed as well as wages in order to cut expenses and to limit production in line with prevailing demand at home and a foreign market that has almost ceased to exist. These unemployed millions are not in position to consume the same quantity of livestock products as when they were receiving regular wages. As a result, the livestock producer has lost an important part of his American market as well as most of his foreign market.

The depression has forced farmers to maintain or increase agricultural production, while at the same time manufacturers have been compelled to curtail industrial production. If the farmer could trade his surplus of hogs for a surplus of automobiles, farm machinery, furniture, etc., there would be no need for farm relief. But no one has been able to work out an acceptable scheme that would result in the creation of surpluses of industrial products comparable to those of agriculture.

On the other hand, the Agricultural Adjustment Act does make it possible for farmers to work out a joint program for controlling agricultural production—something they could not do as individuals. Such a program can be expected to increase prices received by farmers and to augment agricultural incomes as well. Hog farmers will get a larger total income from the sale of 40,000,000 hogs than from 50,000,000. Their costs of production will be substantially less, and they will not have to put in such long hours. If hog numbers are to be reduced, corn production also should be curtailed sufficiently to offset the reduced need for corn. Otherwise, an additional surplus of corn will be built up which would result, no doubt, in increased production of livestock products other than hogs.

In fact, a substantial reduction in corn and other feed crops over a period of several years is needed to bring about a reduction in the numbers of all classes of livestock on farms. Such a program, however, would require several years to effect a reduction sufficient to bring about the desired increase in farm prices.

The Agricultural Adjustment Act provides no means of financing a program to reduce feed-crop production. Payments to farmers for reducing production can be made only on "basic" agricultural products. Corn is the only feed crop designated as basic in the present Agricul-

tural Adjustment Act. Revenues for such a program can be raised from processing taxes on basic products. Only a small sum can be raised from processing taxes on corn, as so little of the crop is processed.

Steps in Developing Corn-Hog Program

After the new administration was inaugurated in March 1933 and it was apparent that the special session of Congress would pass some kind of agricultural-relief legislation along the lines of the domestic-allotment bills considered by committees of the former Congress, the Secretary of Agriculture asked the Bureau of Agricultural Economics to set up committees to develop a practical program for each of the basic commodities.

A conference of agricultural economists of the Corn Belt was called in Chicago, May 15-16, to consider the development of a practical program for reducing corn and hog production as a means of advancing both corn and hog prices toward a fair exchange value as designated in the act. The extremely wet, late spring had so delayed corn planting that a short corn and feed crop was in prospect. It was suggested, therefore, that no effort be made to reduce the 1933 corn acreage, but that plans be worked out to effect a reduction in the 1934 acreage.

Corn-hog producers of the 10 Corn Belt States held State conferences during June and early July and elected representatives to a national conference. The national conference was held in Des Moines, Iowa, July 18-19, 1933. Each Corn Belt State was represented by delegates equal in number to its proportionate production of corn and hogs. At this conference resolutions were passed requesting action on corn and hogs under the Agricultural Adjustment Act. This conference stressed the importance of raising hog prices during the fall and winter. Since corn prices were about at their peak when this conference was held, little thought was given to ways and means of supporting corn prices. A producers' committee of 25 was appointed to assist the Agricultural Adjustment Administration in developing a practical program.

This committee of 25 met with the Agricultural Adjustment Administration officials at Chicago July 20-21. The corn-hog situation was reviewed, and the various proposals for raising corn and hog prices that had been received by the administration were considered.

In order to bring about an increase in hog prices during the fall and winter, it was proposed that the Administration purchase 1,000,000 bred sows, paying the market price plus a bonus of \$4 per head, and also purchase 4,000,000 pigs weighing from 25 to 100 pounds each at a price well above the market. The Administration under this program purchased 6,200,000 pigs and about 225,000 sows during a period of about 6 weeks ended October 1. The edible part of the larger hogs was disposed of for relief purposes. The program cost the Agricultural Adjustment Administration about \$35,000,000.

It was pointed out that these measures were temporary only and that a program to control both corn and hog production in 1934 and later, must necessarily follow this short-time program. In fact, any increase in hog prices by direct removal of market supplies would make a more comprehensive long-time program absolutely necessary. An increase in hog production would be brought about in 1934 and later, unless corn prices were increased correspondingly.

It became more and more evident that the problem of hog production control must be attacked directly. It would not be safe to depend upon the program to reduce only corn acreage as the sole means of decreasing hog farrowing in the spring and fall of 1934. Although the difficulties of administering the allotment plan on hogs seemed almost insurmountable, it gradually became the conviction of those working most closely with the corn-hog problem that such a plan was necessary.

On October 17, a combined corn-hog adjustment plan requiring participating farmers to reduce their corn acreage by at least 20 percent, and hog farrowings by at least 25 percent in 1934, was announced by the Secretary.

The Program

Under the corn-hog reduction plan the producer agrees:

1. To reduce the acreage planted to field corn in 1934 on the farm covered by the contract not less than 20 percent below the average acreage planted to corn on the farm in 1932 and 1933. Corn reduction payment shall be made only on a number of acres not in excess of 30 percent of such 1932-33 average corn acreage, unless authorized by the Secretary.

2. To reduce in 1934 the number of hog litters farrowed 25 percent below the annual average number of litters owned by him when farrowed in 1932 and 1933; and to reduce the number of hogs produced for market from such 1934 litters 25 percent below the annual average number of hogs produced for market from such 1932-33 litters.

3. Not to increase on this farm in 1934 above 1932 or 1933, whichever is higher; (a) the total acreage of crops planted for harvest, plus the contracted acres; (b) the acreage planted to each crop for sale, designated as a basic commodity in the act; (c) the total acreage of feed crops other than corn and hay; (d) the number of any kind of livestock other than hogs designated as a basic commodity in the act (or a product of which is so designated) kept on this farm for sale (or the sale of product thereof). And not to increase the number of feeder pigs bought in 1934 above the average number for 1932 and 1933.

4. Not to increase in 1934 the aggregate corn acreage on all other land owned, operated, or controlled by him which is not covered by a corn-hog reduction contract above the average acreage for such land for 1932 and 1933; and not have any vested or contingent interest in hogs located on land not owned or operated by him.

5. Not to use the contracted acreage except for planting additional permanent pasture; for soil-improving and erosion-prevention crops not to be harvested; for resting or fallowing the land; for weed eradication; or for planting farm wood lots.

The Secretary of Agriculture, upon proof of compliance, shall:

1. Pay for each contracted acre, 30 cents per bushel of estimated yield of corn, less the pro rata share of the county administrative expenses, in two installments: 15 cents per bushel as soon as practicable after the contract is accepted by the Secretary, and 15 cents per bushel, less pro rata share of expenses, on or after November 15, 1934. (The estimated yield of corn on contracted acreage will be determined by an appraisal of the productivity of the land, in terms of bushels of corn, under the average weather conditions of the last 5 years. The appraisal will be made by the community committee. The producer may select the field or fields to be rented to the Secretary.)

2. Pay \$5 per head on 75 percent of the annual average number of hogs produced for market from 1932-33 litters, less the pro rata share of county administrative expenses, in three installments: \$2 per head as soon as practicable after this contract is accepted by the Secretary, \$1 per head on or about November 15, 1934; and \$2 per head on or about February 1, 1935, less the pro rata share of county administrative expenses to be deducted from one or more of these payments.

A program is now under way to inform all corn producers and commercial hog producers as to the principal provisions of the corn-hog production control plan and give all qualified corn and hog producers in the United States an opportunity to participate in the plan, if they

so desire. The intensive campaign, however, will be confined for the most part to the Corn Belt States.

The program is being financed largely by (1) a processing tax on hogs starting with \$0.50 per 100 pounds on November 1; \$1 on December 1; \$1.50 on February 1; and \$2.25 on March 1, and thereafter until October 31, 1935; (2) a processing tax on corn starting with 5 cents per bushel on November 1, to be raised to 20 cents later, depending to some extent on whether or not compensating taxes are levied on starches and sugars not made from corn; (3) compensating taxes on beef cattle, calves, sheep, and lambs, as well as on vegetable oils used as shortening.

Probable Effectiveness

It is expected that corn production in 1934 will be reduced by from 300,000,000 to 400,000,000 bushels below what it otherwise would be without the plan in operation. Although the plan provides for adjustment payments on approximately 500,000,000 bushels of corn, it is reasonable to expect that the reduction on farms that participate in the plan will be offset in part by increased production on the part of farmers who do not come in on the plan.

In anticipating the influence of this plan on corn prices in 1934 and 1935, certain facts should not be overlooked. The corn crop of 1933 is only about 300,000,000 bushels below average. Other feed crops, as well as forage and pasture crops, were exceptionally short in 1933. More nearly normal growing conditions are likely to prevail in 1934. The expected reduction in hogs will reduce the demand for corn by between 100,000,000 to 200,000,000 bushels.

The hog-reduction program is likely to be aided by the general pull of economic forces. The shortage of 1933 corn and feed crops in certain areas such as South Dakota already has resulted in a material reduction in hog numbers in these areas. The program to loan farmers 45 cents per bushel on corn stored on the farm has already resulted in bringing some hogs to market at lighter weights than usual and may be expected to reduce breeding of sows for spring farrow. A reduction of from 15 to possibly 20 percent or even more in the production of hogs in 1934 appears to be a reasonable expectation at this time. Without the allotment plan on hogs it is doubtful whether the reduction would exceed 5 percent.

In considering the influence of this plan on hog prices, the plan as a whole must be given consideration. The emergency program of removing 6,000,000 pigs and 225,000 sows along with the purchase of hog products for relief purposes is expected to remove from 15 to 20 percent of the 1933-34 market supply of hogs from the normal channels of distribution. The influence of this reduction in supply in both the 1933-34 and 1934-35 seasons is expected to be more than sufficient to offset the influence of the processing tax on hogs that is being used to finance this program, thereby benefitting all hog producers whether they participate and receive adjustment payments or not.

CHARLES F. SARLE,
Agricultural Adjustment Administration.

COTTON of Egyptian Type The acreage available for crop
is Noncompetitive Crop production in Arizona and
for West's Irrigated Lands southern California may be considerably increased after completion of Boulder Dam, to say nothing of other irrigation projects under consideration in that section. It is important that this land be devoted, as far as possible, to special crops that cannot be grown profitably elsewhere in the country. Thus only may we avoid the risk of adding to the crop surpluses that have become such a burden to American agriculture. The climate of this section, with its high summer temperatures and extremely dry atmosphere, is not duplicated elsewhere in the United States, but is similar to that of the Mediterranean region, where we should look first for noncompetitive crop plants for the Southwest. Egyptian cotton is among the most promising of these.

This special type of cotton, developed in Egypt nearly 100 years ago, has long been recognized as one of the most valuable of the world's cottons. The length, strength, and fineness of the lint adapt it to the manufacture of such products as sewing thread, tire fabrics, airplane fabrics, and fine dress goods. During the last 5 years our annual imports of cotton from Egypt have averaged 163,000 bales. The United States Department of Agriculture has proved that Egyptian cotton can be grown successfully under irrigation in Arizona and California and that it is not adapted to the Southeastern States.

Starting with seed imported from Egypt, the Department developed the Pima variety, which is grown commercially in Arizona. Since the production of sea-island cotton ceased in continental United States, Pima ranks as the longest in staple of our cottons, the lint measuring $1\frac{1}{16}$ to $1\frac{1}{2}$ inches. There have been many vicissitudes in the production of Pima cotton. During and immediately after the World War it was in great demand by tire manufacturers, and, in 1920, 240,000 acres were grown in Arizona and California. At that time, however, a technic was developed that made it possible to produce satisfactory tire fabrics from shorter cottons, and the demand for Pima ceased, almost overnight.

New Demand Developed

Recently this cotton has found sufficient favor with manufacturers of women's dress goods and men's shirtings to afford a steady demand for the 10,000 to 30,000 bales produced annually in Arizona during the last 5 years. Shirt makers, mail-order houses, and department stores advertise products as made from Pima cotton, and the extension service of the University of Arizona is endeavoring to educate the consuming public as to the greater durability and the superiority in other respects of Pima fabrics. These efforts may stimulate enough demand for this cotton to justify a considerable increase in the acreage. In fact, there is a potential demand for more Pima cotton, but it is not realized, because the smallness of recent crops makes manufacturers hesitate to fill large orders with this cotton, fearing that they may be unable to obtain the quantity required. With larger production, buyers would have a wider range of selection and hence better opportunity to supply mills with the required quantity of cotton of the precise grade and character desired.

Another deterrent to increased use of Pima is the unsatisfactory condition in which much of the lint reaches the market, owing to careless

picking and roping and knotting of the lint in the process of ginning. Apparently methods that have worked well with short-staple cotton cannot be used successfully in ginning the long-linted Pima. Not a few manufacturers who have used this cotton have turned from it because of faulty preparation. They contrast the cleanly picked, smoothly ginned, and carefully baled cotton of Egypt with the careless processing given to this fine product of Arizona farms. A concerted effort to remedy these conditions is now being made.

Even if existing obstacles to increased use of Pima were overcome, however, the market for so long a cotton is necessarily limited. To justify a very substantial extension of the acreage devoted to Egyp-

FIGURE 33.—Lint combed out on seeds, showing the length in the S×P cross (middle) relative to that of the parent varieties; Pima (upper) and Sakel (lower).

tian-type cotton in the Southwest, other varieties, meeting other manufacturing requirements, seem to be needed.

Manufacturers of certain products, notably sewing thread, claim that Pima cotton is not adapted to their needs and prefer the Egyptian Sakellaridis (or Sakel), which has somewhat shorter but very strong and fine lint. This variety has been tested in Arizona, but as compared with Pima it is less productive and later ripening and has smaller bolls. Endeavoring to combine the productiveness of Pima with the lint qualities of Sakel, the Department of Agriculture crossed the two, and, from this cross has developed a new variety, designated provisionally S×P (Sakellaridis×Pima). This variety is at least equal to Pima in yield and earliness and has larger bolls, a higher percentage of lint, and smoother seeds, making it easier to gin. From the grower's point of view it therefore appears to be a satisfactory cotton for southwestern

irrigated lands. The lint is about $1\frac{1}{2}$ inches long and is very fine and strong (fig. 33). Preliminary mill tests indicate that it may prove acceptable as a substitute for Sakel, but more extensive manufacturing experience is required before this can be determined. It has been estimated that if the results of such experience are favorable there is a potential market for from 20,000 to 40,000 bales annually.

Not Expected to Replace Pima

It is not thought that the new variety, even if it responds to present expectations, will replace Pima, which has longer lint and seems especially adapted to the requirements of manufacturers of dress goods and shirtings. It would be desirable to have both varieties grown in the Southwest, in order to supply different branches of the textile industry. If this can be realized, Pima and S×P must be confined to separate districts, since these varieties are so much alike in plant characters that it would be impossible to maintain pure seed of either if they were exposed to mutual cross-pollination in the field and to the mixture of seeds at the gins.

THOMAS H. KEARNEY, *Bureau of Plant Industry.*

COTTON-Volume Reduction Should be Supplemented by Quality Improvement

Favorable price reactions are expected from reducing the volume of the cotton crop, but returns to the growers may also be increased by producing better staple. The importation of long-staple cotton from foreign countries would not be necessary if our system of production were properly adjusted to utilize our natural resources and to provide our textile industries with suitable raw material. That a scarcity of good staples and a surplus of inferior fiber should occur at the same time shows the lack of adjustment.

The production of better fiber depends primarily upon the planting of good seed, and from this standpoint the system of production has changed for the worse since the Civil War. The custom gins, on account of greater mechanical efficiency, replaced the private plantation gins, but the effect of mixing seed from different farms was not recognized until a general deterioration of the crop had taken place, which later was intensified by the arrival of the bollweevil. Varieties that produce better staples were replaced in many districts by short-linted early varieties, or by irregular mongrelized seed stocks, and at the same time essential precautions in growing and ginning good fiber were disregarded. Districts that formerly produced the longest and finest fiber have in recent years only added to the surplus of short or irregular cotton.

An important adjustment of the system of production is made when the farmers of a community adopt a single variety of cotton, since this opens the way to a definite improvement of fiber quality. A unified community can standardize its product by maintaining a uniform seed stock, and thus is able to establish a practical utilization of a superior variety of cotton. Plantings of better varieties by scattered individual growers are of little effect in producing better staple, because the varieties are soon mixed at the gins and cross-pollinated in the fields. The cotton of the district continues to be irregular instead of becoming more uniform.

Advantages of Single-Variety Communities

The single-variety communities obtain advantages in the marketing of their cotton as soon as the quantity of uniform fiber is sufficient to attract the buyers, but the true extent and value of such improvements are not fully appreciated until the community undertakings are carried to the stage of supplying manufacturers with regular quantities of uniform fiber through periods of years. Without a basis of confidence in sufficient supplies of good cotton being available, only a limited use has been possible, while the industrial needs of better and more uniform staples undoubtedly are much greater.

Uniformity of cotton does not mean that the individual fibers are of the same length, even on the same plant or on the same seed. Many short fibers are found among the long fibers, but it is important to have a regular proportion of the staple-length fibers, so that uniform threads may be spun and uniform fabrics woven, with a minimum of breakage in the mill operations. In a uniform variety of cotton the plants are alike and produce fiber of the same character, in contrast with the irregular fiber produced from mixed seed stocks.

The precautions that are necessary to assure uniformity of fiber include the breeding of varieties, the continued selection of progenies to maintain the true type of the variety, and isolation and roguing of seed increase fields. Choice of suitable land is essential to the production of good staple, because equable supplies of soil moisture are required for normal development of the fiber. Checking the growth of the plants injures the developing bolls and damages the fiber. Injuries to the plants and the bolls are readily recognized in the field, and a system of field inspection is being developed in the irrigated districts to keep the good cotton from being mixed with damaged fiber.

Communities that produce better staples have a practical interest in keeping cotton from being planted on unsuitable land, and this is a problem of adjustment like that of reducing production to meet commercial demands. A gradual substitution of better staples in responsible communities is desirable, to allow industrial uses to develop, instead of being discouraged by irregular fiber and by sudden alterations of scarcity and superfluity, such as have occurred in the past. Communities of farmers who have found it possible to unite on a variety of cotton and to change their systems of production and marketing of better staples, may also be able to devise methods of adjusting their crops to the industrial requirements, as a normal precaution of production.

O. F. COOK, *Bureau of Plant Industry.*

COUNTRY Banking in Need of Fundamental Change in Methods

The break-down of country banks during the depression may be traced largely to three factors. The first is the tremendous decline in farm incomes and property values, which reduced bank deposits and undermined the security for bank loans and investments. The second is the fact that country banks were in frozen condition even before the depression set in, owing largely to the fact that they were combining an extensive savings and investment banking business with their commercial banking business. The third is poor management, indicated by the grant-

ing of excessively large loans to individuals, overexpansion of loans in relation to the deposits, undue use of the banks' funds by officers and directors, and other types of indiscretion.

Declining farm incomes, combined with "fright" withdrawals, caused bank deposits to fall precipitously during the depression, and this put an exceedingly heavy strain upon country banks (fig. 34). To meet the decline of deposits, it was necessary for the banks to collect loans, many of which were never intended to be collected in so short a time, and to dispose of bonds and other assets which were primarily investment securities. Thousands of country banks were unable to liquidate enough assets to meet deposit withdrawals. Even highly rated bonds lost much of their value during the depression, and loans that had been considered good but slow proved largely uncollectible. It may be said, consequently, that the depression was a major cause of country-bank failures.

FIGURE 34.—Deposits of member banks located in places of less than 15,000 population.

But this is true only in a limited sense. The depression caused banks to fail because the banks were not in liquid condition before the depression began. As a class, country banks were overburdened in 1929 (and had been for many preceding years) with a tremendous volume of real-estate loans, unsecured "capital loans", and advances of other kinds that could not be quickly liquidated. Some of them had substantial holdings of bonds, most of which are liquid only when the demand for investments is sustained. The banks were not prepared before the depression to liquidate many of their assets at short notice, and they were even less able to do so during the depression, when deposit withdrawals required liquidation.

More Liquid Condition Necessary in the Future

If relief from bank failures is to be attained for the future, country banks must be maintained in a more liquid condition. This may require a drastic reorganization of country banking. Under the present set-up it is almost impossible for a country bank to be in highly liquid condition, owing to the fact that such banks are so largely savings and investment institutions. Seldom, if ever, can a bank find liquid

loans in its community in sufficient volume to employ both its savings deposits and the loanable portion of its demand deposits. Some banks can go outside their own communities and obtain liquid loans, but when all banks are taken into the picture, the volume of bank deposits is far greater than the volume of liquid loans. As a result, commercial banks usually have to invest the savings funds in just the same way as would a savings bank—in mortgages and bonds.

The downfall of country banks was caused by bonds, mortgages, and other slow assets. Investments of these types have been the principal source of loss to country banks, and have been so unliquid as to prevent the banks from meeting their obligations. Examiners often have criticized country banks for having such a large volume of slow loans, but criticism has done little good since the banks had more lending power than could be used in liquid transactions.

It should be understood that bonds, mortgages, and even unsecured capital loans are not necessarily more hazardous than other types of advances when held by institutions which need not sell or collect them at any particular time. They are, however, an extremely hazardous type of asset for commercial banks, which are most likely to be called upon for liquidation at the very time when liquidation is most difficult. To put country banks in liquid condition, such assets must be reduced to a very small volume. This means in many cases at least, that country banks ought not to handle time and savings accounts, and that they should be required to rid themselves periodically of assets that are not based on current agricultural, business, or industrial operations.

It may not be generally known how deeply country banks are immersed in savings and investment banking. A few figures will make this clear. As shown in the chart of bank deposits, more than half the deposits of country banks consist of time and savings accounts, now as well as at earlier dates. Not only is this true, but country banks handle a much greater volume of savings funds than are entrusted to all other local savings and investment institutions. In the southern, middle-western, and western divisions of the country, which most accurately reflect the situation in agricultural communities, country banks hold about two thirds of all savings funds deposited in local institutions.

Investment Business of Country Banks

Far from being mainly commercial institutions, country banks are largely savings and investment institutions. They have assumed this position partly for the convenience of their patrons, and partly in the effort to get as much business as possible. The convenience of having all kinds of banking service available at one bank is self-evident. Moreover, in some small communities there is not enough business of all kinds to support more than one banking institution. To these reasons for combining savings and commercial operations in single institutions, bankers have added their natural desire to build their banks up to the largest possible size.

It cannot be denied that the convenience and economies from combining both commercial and savings banking under one roof have been considerable. Moreover, in farming communities the need for long-term credit is so great that some type of local institution for extending this credit is an actual necessity. But the cost in disrupted banking facilities which has resulted from having the savings business in commercial banks shows that the arrangement is a very dangerous one. It

would be far safer to have a definite segregation of commercial business in commercial banks, and savings and investment business in savings banks and loan companies. Country banks cannot safely handle the slow assets that go with a savings business, for even the savings deposits of country banks are supposed to be payable at short notice.

This is said with full appreciation of the fact that numerous country banks have handled such accounts successfully, even during the present depression, and that there probably will never be a time when all bank deposits are demanded within a short period. Experience has shown, however, that large withdrawals of deposits always occur during severe depressions, and that many bankers who are accustomed to having slow loans in large volume will allow their institutions to become excessively unliquid. Moreover, the banks which have remained open in most cases did not sustain such great deposit declines as did those which closed. The strength of banks cannot be judged alone by the fact that they remain open.

The safest policy for both bankers and their patrons is to have the savings deposits in savings institutions, and to have commercial banks liquid at all times. This incidentally would greatly improve the quality of commercial-bank examinations, because assets would then be judged mainly on the basis of liquidity rather than on the basis of security. The failure of assets to liquidate within a reasonable period would be evidence that such assets should be collected, sold, or charged off immediately.

Changes Should Be Gradual

Such a change in country banking could not be accomplished without great difficulty or without sacrifice by many different interests. Some banks could specialize in savings banking for instance, and relinquish their commercial business to other institutions that were specializing in that field. But, in many cases where exchanges of assets and liabilities might be necessary, it would be hard to divide the businesses of existing banks, owing to differences of opinion over the value of assets. In any case, such a reorganization of banking should be attempted only gradually, for an abrupt change would have serious effects upon the existing system of country banks.

Separation of commercial and savings banking would produce a far better type of commercial banking than we have ever had in the past. Instead of being burdened by a large volume of unliquid assets and heavy fixed charges for time and savings accounts, commercial banks would hold mainly loans that represented advances for the current-production operations of farmers and of local business men. These would liquidate as the productive processes were completed, thus making funds available for the next season's operations. If prices fell or if business activity were reduced, so that deposits declined, the banks would not lend so liberally. But with reduced prices the patrons would not need nor want such liberal credit for production purposes; hence the restriction of credit would do little harm.

Neither borrowers from commercial banks nor the commercial banks themselves would be put under the pressure that results when savings depositors try to withdraw their money, for there would be no savings accounts in commercial banks. Such accounts would all be in savings banks or loan companies, which in turn would be the source of long-term loans to local farmers and business men. These institutions should

be permitted to restrict payments to depositors if necessary to prevent wholesale foreclosures of loans or sacrifice of the interests of depositors who were not trying to withdraw their money. It may as well be recognized that no large volume of savings funds can be paid in a short time by any type of banking system. Such funds are invested in the long-time processes of agriculture and industry and they cannot be withdrawn at short notice.

If any commercial bank were to sustain a run, it could obtain help from a city correspondent or a Federal Reserve bank. Its assets would be of the liquid type which those institutions are glad to accept. This would represent a great change from the present situation. Although country banks now can get some help in such emergencies, their assets are so largely unliquid that this assistance is not sufficient to pay off a large proportion of their depositors.

Reform Would Benefit Farmers

To summarize briefly, a complete separation of commercial banking from savings and investment banking would accomplish two very beneficial results for farmers: (1) It would create liquid commercial banks that could remain open in hard times as well as in prosperous times. This would protect depositors against loss and provide farmers who are good credit risks with more reliable borrowing facilities. (2) Borrowers who needed long-term credits could obtain them on better terms than in the past. Such credits would be extended by savings banks and loan companies, and would not need to be of the short-dated kind so commonly required by commercial banks. Both this feature and the fact that savings banks and loan companies would be less susceptible to runs would protect farm borrowers from the pressure that commercial banks have so often been forced to apply when depositors were withdrawing their money.

FRED L. GARLOCK,
Bureau of Agricultural Economics.

CRESTED Wheatgrass Useful in Northern Great Plains Pasture

During the World War, when the demand for wheat was great and the price high, millions of acres of native sod, mainly in the Great Plains and Mountain States, were plowed and sown to that crop. With the decline in the price of wheat following the war period much of this land was abandoned, since, with the limited and uncertain distribution of the rainfall, crop production is hazardous and yields are likely to be so low as to result in financial loss to the producer when normal prices prevail. That this land was ever broken is indeed unfortunate, as many years of grazing—the use to which it is primarily adapted—have been sacrificed for a few years of profit from cultivated crops. Ranchers have shown little enthusiasm about getting these areas back into grass, and as native grasses do not become reestablished for many years, the land for the most part has been occupied by weeds, mainly annuals of little value for grazing, and has been more or less a prey to erosion.

In the search for a grass that can be utilized for such areas, crested wheatgrass (*Agropyron cristatum*), a long-lived perennial bunch grass, introduced from the steppes of Russia by the United States Depart-

ment of Agriculture in 1898, has appeared most promising. This grass is a close relative of slender wheatgrass (*A. tenerum*) and western wheatgrass (*A. smithii*), both native to our northern Great Plains. It excels all other grasses in cold and drought resistance. No winter injury has been noted even at temperatures of -50°F . It starts about 10 days earlier than most other grasses, and with favorable moisture conditions it produces considerable fall growth. During the hot, dry periods of midsummer it becomes dormant without any apparent injury to the plant, since vigorous growth is resumed when rains occur. When it is grown in conjunction with a grass that is more productive during the summer the grazing season is materially prolonged. Crested wheatgrass has much better seed habits than other grasses commonly cultivated in the northern Great Plains, producing seed in abundance where conditions are even moderately favorable, and presenting no particular difficulties in harvesting, threshing, and cleaning the seed. Its remarkable root system, which so completely occupies the soil, prevents weeds and other plants from becoming established and is also probably a factor in the cold and drought resistance of the grass.

Extended tests made by the United States Department of Agriculture indicate that the grass is best adapted to the northern Great Plains. In sections of low rainfall in eastern Oregon and Washington it has also given good results. The southern limit of the grass has not been definitely determined, though it is doubtful whether it will succeed south of Kansas and Colorado except at high altitudes. It has given no evidence of being a competitor of timothy, orchard grass, and certain other grasses in regions of more abundant rainfall.

Crested wheatgrass is palatable to livestock either for grazing or for hay. When it is grazed, the returns from meat or milk exceed those from native grasses, and the yields of hay are usually greater than from brome grass and slender wheatgrass. The grass is especially promising as a cover to prevent soil and wind erosion and for controlling weed growth in formerly cultivated fields and on badly overgrazed range lands.

Cultural and other detailed information may be found in United States Department of Agriculture Technical Bulletin 307.

C. R. ENLOW and H. L. WESTOVER,
Bureau of Plant Industry.

DAIRY Cow's Udder Studied to Establish Development Standards

The cow's udder provides one of the most important food products and is the source of the largest single item in the Nation's farm income, amounting to \$1,260,000,000 in the depression year 1932, yet comparatively little is known about how the udder develops or how it functions.

The extreme variation in udder development and in the producing capacity of individual cows is well known to those acquainted with dairy farming. Marked variations in the visible udder development of individual heifer calves also, are common observations in almost every herd of dairy cattle. Many breeders and judges of dairy cattle are inclined to look with favor on the precocious udder in the young heifer and to attach considerable importance to that condition. Presumably this preference is based on the assumption that advanced

udder development in the calf is indicative of superior udder development and activity of the cow. As a matter of fact there is little, if anything, in the way of scientific data to support such an assumption. An article by Macmonnies⁴ based on his studies of the show ring, indicates that the highly conditioned young heifers and bulls that win in the show ring are seldom heard from later, and that "as for the fat little udders so frequently seen and seemingly demanded on our unbred heifer calves, I have yet to see the first one that developed into a great working vessel in later years."

The foregoing comments about advanced development of the udder refer to its appearance. The external appearance of the calf's udder, however, is likely to be very deceptive because a heavy deposit of fat beneath the skin may give the udder a semblance of exceptional development whereas the quantity of gland tissue may really be small. On the other hand, udders that appear to be retarded in development may actually contain an abundance of gland tissue in cases where the fatty deposit is scanty. It is necessary for these reasons to distinguish between deposits of fat and mammary-gland tissue in making any study of the significance of advanced mammary development.

Method of Studying Mammary Gland Development

Several years ago the Bureau of Dairy Industry commenced a study of the comparative mammary development of the udders of the heifers in the breeding herd at Beltsville, Md., giving particular attention to the glandular tissue in the udder. Examination of the udders were made at 2 weeks, and at 1, 2, 3, 4, 5, 6, 9, 12, and 18 months of age. Since it obviously is not possible to slaughter the calf for dissection and to obtain lactation records on the same animal, all examinations had to be made by palpation, the observer relying on his sense of touch in making his observations of the stage of mammary development. This study soon showed that the mammary tissue passes through definite stages of development, and revealed differences in the glandular development in the udders of individual calves only 3 or 4 months old that were relatively as great as one would expect to find in the mammary development of mature cows.

In order to determine the significance of these differences in mammary development it was necessary first of all to study the different stages through which the mammary tissue develops, and establish a standard or normal with which to compare the individuals, and then to study the comparative development of each individual at different ages in relation to capacity for production as subsequently measured by milk- and butterfat-production records.

As a check on the observations made by palpation, a number of heifers were obtained for slaughter. These, together with breeding-herd calves that died, provided specimens at most of the ages at which regular examinations were made in the living animal. The mammary-gland tissue of these heifers was dissected away from its surrounding tissues in such a manner as to enable one to visualize the glandular development that previously had been "observed" with the finger tips. The appearance of the dissected specimens corresponded closely with the observations obtained by palpation.

⁴ MACMONNIES, W. DO OUR SHOW HEIFERS MAKE GREAT COWS? *Jersey Bulletin and Dairy World* 10 (2):63. Jan. 12, 1921.

How the Mammary Gland Develops

The mammary-gland development in the young calf appears to begin with a small tubular formation that feels like a tiny cord, leading from the teat upward toward the abdominal wall. This is called the "straight-tube" stage of development. Sometimes an irregular mass of soft tissue may be felt along the abdominal wall, but this does not appear to have any direct association with the subsequent development of the mammary tissue. The straight-tube stage ordinarily continues until the calf is at least 1 month old—sometimes considerably longer. After a time an enlargement can be detected near the center of the straight tube. At first the enlargement is likely to be in the form of a slight bulge which tapers off toward the ends, giving it a distinctly elongated shape. Soon the enlargement takes on a rounded shape, though many retain a slight tapering at the ends for some time.

The various stages of development are illustrated in figure 35.

Although the line of demarcation between the rounded enlargement and the quarter stage is not always distinct, about half the udders examined have definitely passed into the quarter stage at 2 months of age. Very soon the glandular tissue assumes the shape and proportions of the mature udder, that in the front quarter being shallow, and that in the rear quarter being deep. It is interesting to note that the udder, at such an early age, shapes itself to fit the curve of the abdominal wall. The glandular quarters, which are entirely distinct at first, increase rather rapidly in size. The front and rear quarters on each side approach each other and finally become joined at the base, leaving a comparatively large and usually distinct V-shaped depression above. The glands at this time are considered in the half-stage of development. The right and left halves approach each other and sometimes appear to become partially joined but remain entirely separate as far as their ductal systems are concerned; in fact they are separated by a distinct septum of heavy tissue which can be readily seen when the udder is dissected. Each half develops in all directions, gradually filling in the V-shaped depression until it disappears entirely. But in this case also, the ductal systems of the quarters remain entirely independent even though a septum between the front and rear quarters is not visible on dissection.

The development of the mammary tissue from about 2 to 12 months of age is illustrated in figure 36. In *A* and *B* the quarters are distinct; in *C* the quarters show indications of approaching at the base; in *D* the quarters are joined to form a half, but the depression is partly filled; *E* and *F* show slightly more advanced stages; and *G* shows the continuous half.

FIGURE 35. - The various stages of development of the mammary gland: A, Straight-tube stage; B, enlargement stage; C and D, quarter stage; E, F, and G, half stage.

FIGURE 36. — Dissected mammary-gland tissue showing development at different ages: *A*, At 2½ months; *B*, at 3½ months; *C*, at 4 months; *D*, at 5 months; *E*, at 6 months; *F*, at 9 months; *G* at 12 months.

The data obtained since the beginning of the study have been assembled, and a summary of some of the most important items is presented in table 1. Though in reality this is a table of expectancy based on experiences gained in studying the mammary development of a large number of animals, it is presented for use as a standard with which the stage of mammary development of individual Holstein and Jersey heifers may be compared and by which it may be evaluated.

TABLE 1.—Percentage of total number of calves represented in each stage of mammary-gland development, and dimensions of the glandular tissue at different ages

Age group	Straight-tube stage	En-lar-gement stage	Quarter stage			Half stage			
			Per-cent	Width, front	Width, rear	Per-cent	Length	Width, front	Width, rear
	Percent	Percent		Inches	Inches		Inches	Inches	Inches
Holsteins:									
14 days	100	6							
1 month	99	7	2	0.22	0.27				
2 months	62	29	49	.33	.37				
3 months	17	9	78	.44	.52	17	1.79	0.63	0.72
4 months	5	4	44	.56	.66	55	2.33	.77	.83
5 months			19	.63	.80	81	2.78	.93	.94
6 months			6	.63	.88	95	3.33	1.04	1.04
9 months						92	4.73	1.29	1.22
12 months						100	5.56	1.40	1.32
18 months						99	7.09	1.45	1.35
Jerseys:									
14 days	100	8							
1 month	99	9	2	.50	.50				
2 months	56	31	53	.51	.56	3	1.50	.47	.47
3 months	12	7	66	.45	.53	32	1.77	.64	.67
4 months	2	1	31	.51	.59	74	2.23	.75	.78
5 months			7	.60	.72	94	2.78	.86	.86
6 months						100	3.35	.99	.98
9 months						99	4.73	1.19	1.15
12 months						100	5.83	1.32	1.26
18 months						100	8.26	1.47	1.41

The data are grouped according to the age of the animals. The values in the columns marked percent show the proportion of the total number of calves or heifers studied in any age group, whose mammary-gland tissue was in the stage of development indicated in the heading. The dimensions of the tissue in the quarter stage and half stage are given in inches. For a number of ages the percentages for the different stages total more than 100. This is due to an overlapping of the straight-tube, enlargement, quarter, and half stages. For example, it is possible that one udder may have glandular tissue in the tube stage, enlargement stage, and quarter stage at the same time, or an udder may have quarter stages on one side and the half stage on the other. It is noted also that in some instances the percentages for the half stages at ages from 9 to 18 months are less than 100, even though quarter stages are not present. This does not mean that the halves had not been formed, but that a notation as to the presence or dimensions of halves was omitted at the time observation was made. The greatest number of animals studied in any age group is 146 for Jerseys and 97 for Holsteins.

Although the data are not given in this condensed table, there is a period from 2 or 3 to 6 months during which in some cases the front and rear glandular quarters are approaching each other. The percentage in which the quarters are joined increases steadily to 9 months and then declines, but the decline is due to the omission of a record and not to failure of the quarters to become joined. The depression diminishes steadily in size from its first appearance at 2 or 3 months to the obser-

vation at 18 months, indicating that the depression was gradually filled in with mammary-gland tissue.

Table 1 indicates for Holsteins that at 14 days of age every udder was in the straight-tube stage. At 1 month 99 percent were in the straight-tube stage, but a few showed enlargements and quarters. At 2 months the number in the straight-tube stage was greatly reduced, and the number in the quarter stage increased to nearly half. At 3 months the number in the straight-tube stage represented only 17 percent, but although 78 percent were in the quarter stage, there were also about 17 percent in which the quarters had joined to form halves. The 4-month group was the last showing either straight tubes or enlargements, and as age advanced the proportion in the quarter stage decreased and the proportion in the half stage increased, the last quarters appearing at 6 months. The steadiness with which the front and rear quarters increased in width is noteworthy, the front ones in all cases being smaller than the rear ones. The length and width of halves also increased with striking regularity, but the front ones were more narrow in the early stages, became equal to the rear ones in width at 6 months, and thereafter were wider.

The data for Jerseys show that, although in general their mammary development is similar to that of Holsteins, the Jersey percentages for straight tubes decrease more rapidly with advance in age, the proportion in the quarter stage at 2 months is slightly higher, the last appearance of quarters is at 5 instead of 6 months, and the first halves are recorded in the 2-month group instead of in the 3-month group and consistently show higher percentages during the early stages of development. On the other hand the widths of quarters and the lengths and widths of halves are nearly the same for both breeds in most age groups. There is a tendency for the Jersey widths to be slightly lower in the intermediate age groups but to more than equal the Holstein widths at 18 months; and the lengths of halves for Jerseys, after remaining nearly the same during the intermediate ages, become distinctly greater than for Holsteins at 12 months and still greater at 18 months. On the whole the data for the two breeds are remarkably similar, the Jerseys maturing somewhat earlier in life but the quantity of mammary-gland tissue being nearly the same for both breeds, during the first 12 months.

Individual Variation in Mammary-Gland Development

Not only is a breed difference indicated, but the marked variation in mammary development found to exist between individual animals is, to some degree, shown in table 1. For example, all four stages of development are found in both the 3- and 4-month age groups for Holsteins and in the 2-, 3-, and 4-month age groups for Jerseys. Marked individual variations for the different items also are shown by the detailed data not given in the table. For example, in the 3-month group, for Holsteins, the number of straight tubes varies from 1 to 4; the number of enlargements from 1 to 4; the number of quarters from 1 to 4; the width of front quarters from 0.15 to 0.67 inch; the width of rear quarters from 0.25 to 0.75 inch; the number of halves from 1 to 2; the length of halves from 1.33 to 2.25 inches; the width of front halves from 0.42 to 0.79 inch; and the width of rear halves from 0.59 to 0.96 inch. The individual variations for Jerseys are similar, but in most cases even greater than for Holsteins.

Neither the cause of the variations found to exist in mammary development nor their significance is known. The cause may at some time be discovered through a study of genetics, nutrition, or physiology. This study is designed primarily to determine the significance of the variations in relation to the mature development of the udder and to its producing capacity. Results can be obtained only after each of the animals has reached maturity, and demonstrated her milk- and butter-fat-producing capacity. Data are now complete for a few animals. When data for a sufficient number are available, correlation coefficients will be determined which are expected to reveal the significance of advanced or retarded mammary development in the heifer calf. For the present the study has provided standards with which to compare the degree of development in the individual animal.

Practical Importance

The breeder of dairy cattle would consider himself fortunate indeed if, by examining the udder of a young heifer calf, he could predict with reasonable certainty her producing capacity when she becomes a cow. Studies of dairy-herd improvement records indicate that one third of the cows enrolled fail to pay for their keep, one third produce only enough to break even, and only one third pay a profit. Approximately 5,500,000 heifers must be raised each year to provide enough replacements to maintain the present cow population in the United States. Until the time comes when herd sires are used that are more nearly pure genetically for high production it is obviously going to be necessary to cull out at least one third, or almost 2,000,000 of these heifers annually. They will be nearly 3 years old and will have cost from \$75 to \$125 each to raise before their capacity for production can be determined. A conservative estimate of the difference between the cost of raising and the amount received from the butcher would be \$50, but even at \$25 each, the financial loss resulting from raising these 2,000,000 unprofitable heifers amounts to the sum of \$50,000,000 annually, to say nothing of the time and trouble involved. Ability to select at an early age the animals capable of high production would eliminate this loss. The work on mammary-gland growth in the young heifer, though not expected to provide an infallible method for doing so, does have a direct bearing on this point.

W. W. SWETT and C. A. MATTHEWS,
Bureau of Dairy Industry.

DAIRY-RATION Tests Show Importance of Vitamin A in Roughage Work at a number of experiment stations, particularly at the Michigan station, has made it clear that dairy cattle will not thrive on rations composed of grains and concentrates alone. Such rations are deficient in certain nutritive essentials which are most easily supplied either by pasture or by hay of good quality. It is very important, therefore, to discover which kinds of hay or roughage contain these nutritive essentials in most liberal quantities and to learn as much as possible about their chemical and other characteristics.

For the last 15 years the Bureau of Animal Industry and the Bureau of Dairy Industry have carefully studied the nutritive properties of different kinds of hay and roughage. The study has consisted of two

lines of work. In the first place, calves and cows have been fed continuously for long periods on rations composed of grain combined with various kinds of roughage, and their growth, milk yield, reproduction, general health, and longevity have been observed. In the second place, other work has been carried out to determine so far as possible which of the chemical and other characteristics of the roughage used were responsible for the results obtained in the feeding experiments.

The kinds of roughage most extensively studied so far have been the United States standard grades of No. 1 Alfalfa hay and No. 3 Timothy hay. Some work has been done, however, with No. 3 Alfalfa, No. 1 Timothy, No. 1 Clover, and also with pasture and corn silage. Hay of the No. 1 grade is that which has been cut while in bloom or earlier, and cured so that it retains its green color, and, in the case of alfalfa or clover, its leaves. Hay of the No. 3 grade is that which has lost its green color and some of its leaves through being cut in the seed stage, or through being cured under unfavorable weather conditions.

Cows fed on a good grain mixture combined with No. 1 Alfalfa hay, but without pasture, have remained in good health, have reproduced satisfactorily, and have yielded more than average quantities of milk for periods up to 7 years. Cows fed on a similar grain mixture combined with No. 3 Timothy hay, on the other hand, have never survived and remained capable of reproducing and yielding milk for more than 3 years. The usual history has been that they begin to throw premature, weak, and dead calves after about 6 months on such rations, and that in less than 3 years they either fail to breed, or become sick and die. The milk yield usually was not markedly affected in the first year or two, but later it became much reduced in those cows in which it was possible to obtain pregnancy.

Experiments with Calves

In the case of calves, such feeding experiments are complicated by the fact that it is necessary to feed milk in the early stages of life, and the results differ according to the kind of milk that is fed. The calves are fed, according to the usual routine, on whole milk up to the age of 30 days, and then on skim milk for the next 5 months. They are offered grain and hay in addition from the age of about 2 weeks on, and usually begin eating fair quantities of these feeds after they reach the age of 3 weeks. Under such circumstances the calves often grow fairly well and survive, if the milk comes from cows that are fed No. 1 Alfalfa hay or are on good pasture, even though the calves themselves receive No. 3 Timothy hay. But if the milk comes from cows whose roughage is No. 3 Alfalfa hay, No. 1 Timothy hay, or No. 3 Timothy hay, and the calves themselves are fed No. 3 Timothy hay, they always fail to grow satisfactorily and die before they are 6 months old. If, however, the calves are fed on No. 1 Alfalfa hay they grow satisfactorily and survive on any of the five kinds of hay mentioned above.

It has, unfortunately, not been possible to obtain enough cattle to study the nutritive properties of No. 1 Clover hay, No. 3 Alfalfa, and No. 1 Timothy as extensively as those of No. 1 Alfalfa and No. 3 Timothy. Some experiments, however, have been carried out with cattle, and additional information has been obtained from experiments with rabbits. Rabbits are very similar to cattle in their feeding habits, and information can be obtained from experiments with them much more quickly on account of their small size and rapid rate of reproduction.

The results with the cattle and rabbits have agreed so far, but can be only very briefly summarized here. No. 1 Clover hay is nearly as good a roughage as No. 1 Alfalfa. No. 3 Alfalfa and No. 1 Timothy are intermediate between No. 1 Alfalfa and No. 3 Timothy. It has not been possible to secure satisfactory growth and reproduction with either cattle or rabbits on rations composed of grain combined with either No. 3 Alfalfa hay or No. 1 Timothy hay, and without pasture or other fresh green feed.

It has been known for a long time that alfalfa hay contains much more protein and much more lime than timothy hay, and that hay of good quality contains somewhat more digestible protein and total digestible nutrients than hay of poor quality. But the experiments of the Bureau of Dairy Industry considered together with those of various experiment stations show that none of these easily demonstrated chemical differences could account for the differences in results which have been obtained in the afore-mentioned feeding experiments.

Significance of Vitamin Content

In the experimental work carried out in the Bureau of Dairy Industry, however, the vitamin A content of the different kinds of hay used has been determined. The results have shown that alfalfa hay contains more vitamin A than timothy, and that hay of the No. 1 grade contains more vitamin A than hay of the No. 3 grade. This work is still in a rather early stage of development, and the figures obtained must be regarded as approximations. They indicate that No. 1 Alfalfa hay contains about 30 times as much vitamin A as No. 3 Timothy hay, while No. 3 Alfalfa and No. 1 Timothy are intermediate in vitamin A content. Other work shows that good pasture contains decidedly more vitamin A than any kind of hay, and that carrots, particularly carrots of a deep-orange or yellow color, are rich in vitamin A.

There are a number of reasons for thinking that the differences in the vitamin A content of the different hays used in the experimental work played an important part in bringing about the differences in the results. In the first place, the grains and concentrates fed with the hay are known to have a much lower vitamin A content than alfalfa hay of good quality. Secondly, it is well known that a deficiency of vitamin A in the food retards growth, interferes with reproduction, and renders animals more susceptible to disease. All these conditions have been observed in the cattle and rabbits fed on No. 3 Alfalfa hay, and on timothy hay. Finally, it has been found that although calves always die when fed on No. 3 Timothy hay combined with grain and milk from cows fed on No. 3 Timothy hay, calves will survive and grow satisfactorily on such rations if cod-liver oil is added to them. There is every reason to believe, therefore, that the vitamin A content of good hay is a potent factor in accounting for its importance in the winter dairy ration, though it would not be wise at the present time to suppose that this is the only important nutritive factor which is present in liberal quantities in good hay, and deficient in grain.

The work of which an account has just been given may be said to show that roughage is the chief source of vitamin A for dairy cattle, that roughages vary greatly in their vitamin A content, and that the dairy farmer must consider just as seriously the vitamin A content of his rations as their content in protein and total digestible nutrients.

EDWARD B. MEIGS, *Bureau of Dairy Industry.*

DAIRY Sires Proved at Earlier Age by Lactation Records

During the last 2 or 3 years dairy specialists and others interested in proving sires in dairy-herd-improvement associations have given considerable thought to the kind of record that should be used in comparing the production of the sire's daughters with that of their dams. Some dairymen have contended that the production of the daughters and the dams should be compared on the basis of their records made during the association testing year, a period of 12 months. Others have contended that the comparison should be made on the basis of their production during one complete and continuous lactation period.

Many studies of the two methods of comparison have been made, by State specialists as well as by the Bureau of Dairy Industry, to ascertain, if possible, their relative merits. The results of these studies are conflicting, and no definite conclusions have been drawn. Since production records are of prime importance in the proved-sire work, the Bureau of Dairy Industry, during recent months, has made a study of the two kinds of records and has observed certain pertinent facts which will aid in the evaluation of the two methods of comparison. From the standpoint of the greatest value to the dairy industry it appears that the lactation method has many features which make it more valuable than the 12-month method.

To be of greatest value to the dairy industry sires must be proved while they are still alive and young. A study of records, selected at random, of 64 sires proved by both methods shows that 30, or 46.9 percent, were proved earlier by the lactation method. The remaining 34 sires were proved at approximately the same time by both methods. It is possible that in herds being placed on test for the first time 12-month records would be available before lactation records. While this is a point in favor of 12-month records the number of sires proved by records from herds just placed on test is practically negligible.

Of the last 832 sires proved in dairy-herd-improvement associations, 23.7 percent of those proved by the 12-month method were still alive when proved while 41.9 percent of those proved by lactation records were still alive when proved. Sires are proved earlier by the lactation method because comparisons can be made as soon as five daughters of tested dams have completed their first lactation period, whereas, with the 12-month method comparisons are not made until the herd-improvement association year has ended and records are summarized, which is usually 6 months to a year later. This lapse in time represents a period very important to the dairyman who is attempting to carry out a progressive breeding program. It is likely to result in an entire crop of calves which may or may not improve the herd. It may mean disposing of a sire that should have been kept or keeping a sire that should have been slaughtered.

No Data as to Comparative Accuracy

Data now at hand fail to show that either method of measuring the production of a cow is superior to the other in accuracy. Some data, however, show 12-month records for the same cow over a period of years tend to have slightly more uniformity. Other data reverse this tendency. Any such uniform tendency is readily explained by the fact that a 12-month record usually consists of parts of two lactation periods, and is therefore somewhat of an average of the cow's production for

the period, whereas the lactation record is an individual figure without averaging influences.

When records are taken by both methods for the same cow for the same period neither method shows superiority in measuring or forecasting the production of the cow in future years. Perhaps when more data are at hand and more studies have been completed one method may show greater accuracy than the other, but as yet no results are sufficiently conclusive to indicate anything other than relative equality of the two methods in this respect.

It has been contended by some that the tester can obtain 12-month records of dams and daughters more easily than he can obtain lactation records and that, therefore, more sires could be proved by the 12-month method. As a matter of fact, to obtain lactation records requires less of the tester's time than to obtain 12-month records. Only five dam-and-daughter lactation comparisons are needed, whereas with the 12-month method the tester must report the records of dams of all daughters on test during the testing year. Not only is less work required of the tester for the lactation records, but the work is distributed throughout the year as the lactation periods may happen to end, while the 12-month records must necessarily be worked out at the end of the year when the tester is busy making out annual reports and summarizing the year's work.

While other points in favor of either method can be found, in the lactation method the time element alone allowing more sires to be proved while still alive and young is sufficient to justify the general use of lactation records in proving dairy sires.

J. F. KENDRICK, *Bureau of Dairy Industry.*

DIET Studies Show Needs that National Planning Must Consider In planning a long-time program for adjusting agricultural production to consumption demands, two major questions arise: How much food—what kinds and how much of each—will it take to provide an adequate diet to all of the people of the United States? How much land and how much livestock will be required to produce this supply?

The health and efficiency of a nation depend upon its diet. Its economic welfare depends to a large extent upon the prosperity of its agriculture. In trying to answer these two questions, we must turn to the researches that have been made on the nutritional requirements of man at different stages of growth and development and under different circumstances. With these physiological needs, we must correlate what we know about the nutritive values of different foods, not forgetting their cost and the quantities it is wise to consume. We must also consider the dietary habits that representative groups of our people are following at different levels of living, as well as the statistics on crop yields, distribution, etc.

A formula for a national-diet plan is therefore based on extensive computations. The first step is to calculate how much of different kinds of food is needed by individuals in order to supply the essential calories, proteins, minerals, and vitamins in good proportions. The Bureau of Home Economics has done this for every age, taking account of the differing needs of adolescent boys and girls, and of men and women doing light or heavy muscular work. The census of 1930 fur-

nishes information on the proportion of the population in different age, sex, and occupational groups. Once the lists are compiled for these groups, it becomes a matter of arithmetic to compute the allowances necessary for the 122 million persons comprising our population. Finally, since the quantities of foods needed by 122 million persons are too large to comprehend readily, the total needs are divided by the number in our population and expressed on a per capita basis.

Flexibility in National-Diet Plans

Naturally, a national-diet plan must be flexible. It must allow for racial and regional food traditions that are worth preserving. It must allow for the different amounts of money that families even of the same make-up and standard of living as their neighbors can or wish to spend on food. Therefore, not 1 but 3 diets have been worked out at three cost levels. Each is stated in terms of pounds and quarts and dozens of important foods or groups of foods. This gives some latitude of choice. These diets as here given (table 2) make no allowance for the unavoidable losses in harvesting, grading, storing, and distributing food. These quantities are for food ready for home consumption.

TABLE 2.—*Approximate yearly quantities of foods needed per capita for the population of the United States in adequate diets at 3 levels of cost*

Item	Adequate diet at minimum cost	Adequate diet at moderate cost	Liberal diet
Flour, cereal.....	pounds 224	160	100
Milk or its equivalent ¹	quarts 260	305	305
Potatoes, sweetpotatoes.....	pounds 165	165	155
Dried beans, peas, nuts.....	do 30	20	7
Tomatoes, citrus fruits.....	do 50	90	110
Leafy, green, and yellow vegetables.....	do 80	100	135
Dried fruits.....	do 20	25	20
Other vegetables, fruits.....	do 85	210	325
Fats, including butter, oils, bacon, salt pork.....	do 49	52	52
Sugar.....	do 35	60	60
Lean meat, ² poultry, fish.....	do 60	100	165
Eggs.....	dozen 15	15	30

¹ The following are approximately equivalent to the food value of 1 quart of fluid whole milk: 17 ounces of evaporated milk; or 1 quart of fluid skim milk and 1½ ounces of butter; or 5 ounces of whole-milk cheese; or 4½ ounces of dried whole milk; or 3½ ounces of dried skim milk and 1½ ounces of butter.

² Retail cuts.

The diet lists show striking differences, as for example, in flour and cereals. The minimum-cost diet calls for 224 pounds per capita, and the liberal diet for less than half as much, 100 pounds. This illustrates, of course, a well-known fact that the less money there is to spend for food, the greater is the dependence on the staple national cereal, whether it be wheat, corn, rice, or oatmeal. But on vegetables, fruits, lean meat, poultry, fish, and eggs, the recommendation runs the other way. The liberal diet has twice as much or more of these foods.

From the nutritive standpoint, all three of these diets are adequate. They furnish enough of the nutrients so far discovered and measurable in quantitative terms, to provide for growth, maintain health, and leave a margin for safety. Naturally, the liberal diet includes the so-called "protective" foods in most generous quantities. It also includes more of the foods that appeal to the eye and the palate. It takes a shrewd shopper and a skillful cook to give variety and appetite appeal

to a minimum-cost diet week in and week out. Fortunately cabbage, carrots, and some other green leafy and yellow vegetables rich in vitamins and minerals and hence high in the "protective" values, are plentiful and cheap. Along with milk, tomatoes, and citrus fruits they help to safeguard the minimum-cost diet with its high proportion of cereals.

Per Capita Cost of the Three Diets

On the basis of retail prices during 1931-32, the per capita cost of the three diets ran \$85, \$140, and \$165 for a year. Judging by family-living studies the majority of families in the United States spend for food about as much as they would have to pay for the minimum- and moderate-cost diets. Records from families on farms and from wage earners living in cities show that their food costs were at this level during the period from 1922 to 1929. Due allowance is made, of course, for price changes and a money value is also placed on the food that the farm families took from their home-raised supplies without cash outlay. Reports also show that during this same period, the families of many skilled wage earners and business and professional workers spent enough to give them the liberal diet. Hence the diets here recommended are not out of line with our food expenditures in normal times. In nutritive value, however, the suggested diets are much higher than those that most families now select.

Acreage Required for the Three Diets

For the second question—how much land and how much livestock are required to produce the food for these diets that measure up to the standards of good nutrition? Preliminary estimates of the Production Planning Section of the Agricultural Adjustment Administration indicate that 2.68 acres of land, not counting pasture land, would be needed per capita to supply the foods for the liberal diet. For the minimum-cost diet, the estimate is 1.79 acres per capita, and for the moderate-cost diet, 2.24 acres. These figures are based on the average per acre yields of different food crops in this country during the 10-year period 1923-32 with an allowance for exports, seed, and for land needed to feed the horses and mules used in producing the foodstuffs, also for waste and shrinkage between farm and kitchen. Pasture lands vary so widely in the number of livestock that they can support per acre that the land requirements for meat production need more careful analysis. On the same basis, 2.27 acres would be required to produce the food apparently consumed per capita each year during the period 1925-29.

Better Nutrition Is the Goal

In our national planning, it is the moderate-cost and the liberal diets toward which we need to work. They would lend stability to our use of land and labor, it is believed. For diets that are very inexpensive to the consumer are largely made up of foods that require relatively little land and labor to produce. They are composed largely of the nonperishable foods, the ones that can be stored for a long time and distributed cheaply, such as grain products, dried legumes, and potatoes. We know, however, that we fall short in our consumption of other foods, notably milk, certain fruits, and many of the leafy vegetables. For our

health's sake, our use of these foods might well be considerably increased several fold.

These more adequate diets if adopted nationally will do much more than just eliminate pellagra, rickets, and the other out-and-out evidences of faulty nutrition. Every year brings increasing evidence that dental caries is chiefly a nutritional problem. There are also many border-line cases of poor health difficult to diagnose, but to which food habits unquestionably contribute. These better diets will take us above our present average and far on the road toward optimal nutrition.

HAZEL K. STIEBELING, *Bureau of Home Economics.*

DUTCH Elm Disease Now Serious Around New York; Entered Country in Logs Since 1919 the Dutch elm disease has been sweeping over Europe, killing elms. It is caused by the fungus *Graphium ulmi*. The leaves wilt or turn brown or yellow, and this is accompanied by a brown discoloration of the young wood. The disease spreads rapidly down the vessels and the tree dies. The fungus is carried from tree to tree by elm bark beetles, which lay eggs and hibernate under the bark of moribund elms, and feed on young healthy twigs.

The disease has been known in the United States since 1930. During that year 3 infected trees were found in Cleveland and 1 in Cincinnati, Ohio. In 1931, 4 more infected trees were discovered in Cleveland. Scouting in 1932 revealed no additional trace of the disease. In 1933, by extensive scouting, but 1 additional infected tree was found in Ohio. All the disease found in Ohio has been eradicated, and the infection there seems to be under control.

However, in 1933 a new and much more extensive outbreak was discovered around New York City. Early in the summer the causal fungus was cultured from specimens taken from a park tree in Maplewood, N.J. Late in 1932 the park foreman had noticed a wilting limb on the elm, which he attributed to the drought then prevailing. But in the following spring, during abundant rain, the whole tree wilted.

As soon as the disease was determined, cooperative arrangements were made with the New Jersey State officials and the local shade-tree commissions. The assistance of technicians and of camp men was obtained from the Civilian Conservation Corps. Funds were secured from the Public Works Administration. An extensive campaign was begun. Soon it was discovered that the disease was also present in New York State.

Until October 31 this infected area, centering in New York City, contained 677 known infected trees. Of these, 628 were in an area that was within about 15 miles of the Hudson River and New York Harbor and extended from Paterson to New Brunswick, N.J. In New York State, Staten Island, Long Island, and the south half of Westchester County were involved, and 48 known infected trees had been found. One tree had been located just across the border line in Connecticut.

A third independent infected region was discovered at Baltimore, Md., where one tree was located on the grounds of Fort McHenry.

One Method of Entrance Discovered

During 1933 one of the most serious handicaps to the control of the Dutch elm disease in the United States was removed. A method of travel of the fungus across the Atlantic Ocean barrier and of entrance into the United States was discovered.

In July 1933 the inspector of the Bureau of Plant Quarantine at the port of Baltimore, Md., discovered elm burl logs that were infested with *Scolytus* beetles. These logs had been imported from Europe for the cutting of fancy veneers. They were destined for the interior of the United States. Examination and culturing of specimens disclosed the presence of *Graphium ulmi* in the wood. Similar interceptions

FIGURE 37.—Elms dying from the Dutch elm disease in New Jersey.

were subsequently made at New York, Norfolk, Va., and New Orleans, La. In these logs one or both of the two species of elm-bark beetles, *Scolytus scolytus* and *S. multistriatus*, which are the principal carriers of the elm disease in Europe, were present, in some cases abundantly. From three of the shipments the fungus *Graphium ulmi* was cultured. It appears that the importing of elm burls for veneer is a movement of rather recent development. The logs come under the name of burl elm or Carpathian elm.

Steps were taken immediately by the Bureau of Plant Quarantine to eliminate this source of entrance of the Dutch elm disease and of its insect carriers, and Quarantine No. 70, effective October 21, 1933, was issued, regulating the entry of such logs by methods believed to remove all risk. The quarantine also forbids or regulates the importation of other parts of the elm and related plants.

The discovery of the entrance of the disease on elm burl logs now makes it possible to understand the present known distribution of the

disease in the United States. The Baltimore infection is not far from the piers where imported logs were unloaded; the Cincinnati and the Cleveland trees were near railroads that hauled imported logs; the New York City infected area surrounds the piers where several shipments arrived, and its most heavily infected section is penetrated by log-transporting railways.

According to the Bureau of Entomology, of the two beetles found in the imported logs but one, *Scolytus multistriatus*, is known to be established in the United States. These beetles burrow between the wood and the bark of unhealthy elms and there lay their eggs, and there the larvae develop. If the tree is infected with *Graphium ulmi*, the fungus produces its spores in these beetle tunnels, and the insects become covered with them. Later the beetles feed around the buds and in the crotches of healthy elm twigs, thus inoculating them with the disease.

FIGURE 38.—Brown ring produced by the Dutch elm disease fungus in the young wood of an elm twig.

Eradication Campaign Under Way

An energetic campaign is now under way to secure the removal of the known infected trees and to discover others. The problem now presents itself in this form: Either we must abandon our effort and reconcile ourselves to heavy losses of the American elm, or we must undertake an extensive, thorough, and whole-hearted cooperative movement to find and eradicate every *Graphium*-infected tree and to reduce to the utmost the elm-bark beetle population which carries the fungus. While about 1,400 square miles are included in the area in which infected trees have been found, the actual percentage of diseased elms is small. In the towns of the New Jersey district, on an average less than half of 1 percent of the elms are known to be infected. Even in the most heavily infected towns not over 2½ percent of the trees as yet are known to have the disease. Many more may be found in 1934.

Success in fighting this disease and saving the American elm requires cooperation from everyone. Clean out and burn all dead wood from your elms. Keep them in a healthy condition. Watch them for wilting or yellow or brown leaves (fig. 37) accompanied by brown streaks in the young wood (fig. 38). Send specimens the size of a lead pencil of any twigs thus affected to your State agricultural experiment station or to the Division of Plant Disease Eradication and Control, 202 Post Office Building, East Orange, N.J., or Room B-32 County Office Building, White Plains, N.Y., or 200 Atlantic Building, Room 316, Stamford, Conn.

R. KENT BEATTIE, *Bureau of Plant Industry.*

EELGRASS Disappearance Has Serious Effects on Waterfowl and Industry

One of the outstanding biological phenomena of recent times has been the sudden and nearly complete dying out of eelgrass (*Zostera marina*) during the past 2 or 3 years along the Atlantic coasts of North America and Europe. The disappearance of this seaweed has forcefully called attention to its importance to waterfowl, its intricate relations to other aquatic life, and its great economic value.

Though eels find shelter within its stands, whence its name, eelgrass is neither eaten by eels nor is it a grass. It is a flowering plant of the pondweed family and grows submerged in brackish waters. Under normal conditions it is the dominant plant of such waters, growing in dense masses on mud flats, which at low tide may be exposed or barely covered, though at high tide they may be under 10 feet or more of water.

The plant's range on the Atlantic coast is from North Carolina (near Beaufort) to southern Labrador, James Bay, and the west coast of Hudson Bay, in Canada. It also occurs on the Pacific coast and in northern Asiatic waters as well as on European coasts, including the Mediterranean Sea. Among names commonly applied to it are seaweed, crabgrass, sea-oar, sea-grass, saltwater-grass, brant-grass, ribbon-grass, tiresome-weed, widgeon-grass, sea-moss, duckweed, grassweed, grass-wrack, wrack-grass, sea-wrack, glass-wrack, barnacle-grass, bell-ware, sweet-grass, turtle-grass, drew, marine zostera, mallow, and alga. The dried plants are also known as hay, sea-hay, sea-sedge, and alva marina.

Importance of Eelgrass

However great the value of eelgrass for economic purposes, this is probably much less than its value in nature. As the dominant plant along much of the coast, it bears an important relation to every creature living in these waters, and thus is also of indirect value to man. It is normally the staple winter food (more than 80 percent) of sea brant, an important food of Canada geese and black ducks, and it is only slightly less important to scaups, redheads, and other waterfowl feeding along coastal waters. The numbers of brant, already seriously reduced by hunting, are so greatly menaced by this curtailment of their natural food supply that the Department of Agriculture has declared a closed season for them in the Atlantic Coast States. Disappearance of eelgrass is also affecting the fishery and shell-fishery industries and has resulted in such erosion of many coastal areas as to alter considerably their surface features.

European history shows that eelgrass had economic uses during earliest times. Ashes of the plant are reported to have been found at ancient village sites in Denmark, burned, it is thought, to obtain salt and soda. On islands deficient in wood, eelgrass has served for fuel. For dwellings near the coasts it was an early form of bedding, and it is still used for filling mattresses and bed ticks. Fishermen and farmers along the coast use eelgrass for bedding domestic animals, and in recent years the dried fiber has had extensive use both in North America and abroad in upholstering and packing and as a compost for fertilizer. In the Netherlands it is said to have had some use in dike construction.

Eelgrass has found its most extensive modern use as an insulating material. In New England it was first used for this purpose by the early

settlers, who banked houses and barns and covered cellar storehouses and other structures with it. For insulation against cold, heat, or sound, it is made into single, double, or triple-ply quilts, sandwiched between layers of tough kraft, waterproof, or asbestos paper. It is used also for wall sheeting in buildings, for roofing and pipe covering, and for insulating gas and electric ovens, fireless cookers, and other domestic apparatus. As a sound deadener it has proved of value in conservatories of music, apartment houses, offices, and hotels. The eelgrass quilts made for these purposes are usually in rolls containing 250 square feet, each roll weighing 40 to 90 pounds, depending upon the thickness. Several patents have been issued for its use in the manufacture of a high-grade paper. During the war, when cotton was hardly

to be had in Germany, the fiber of eelgrass was incorporated into nitrocellulose, or gun-cotton.

Because of the abrupt dying off of eelgrass, there has been practically no harvest during the past few years, but during 1929, which was probably a year of maximum production, two Boston firms alone imported 1,725 tons of the dried plant from Nova Scotia. Other countries important in the production of eelgrass are Great Britain, the Netherlands, and France, the exports from the Netherlands having aggregated 2,000 to 3,000 tons annually. In the United States domestic production

FIGURE 39.—A, eelgrass plants collected December 16, 1932, from a badly diseased stand (crop less than 1 percent normal) in South Oyster Bay, N. Y., showing leaves frayed and rotted off; B, eelgrass collected August 11, 1932, from an apparently normal stand in Hancock County, Maine. (From pressed herbarium specimens.)

between 1913 and 1927 is believed to have been about 5,000 tons annually. The price paid for the dried material delivered at the factory has been \$20 to \$30 a ton. A crop report from France indicates that the price there nearly doubled in 1913, a year in which little eelgrass was produced.

History and Extent of Disappearance

The factor or factors responsible for the destruction of eelgrass plants (fig. 39) may have been operating over a long period. The conspicuous dying out, however, occurred in most localities in 1931 and 1932, with some evidence of the trouble in a few restricted areas late in 1930.

It seems that in midsummer of 1931 in most localities from North Carolina to New England the leaves of the eelgrass became somewhat darkened, broke from their roots, and washed ashore in great windrows. Before that summer was over, less than 1 percent of a normal stand of the plant existed in the sections affected. So far as the writer is aware, such rapidity of spread and destructiveness of a plant epiphytic is not known elsewhere in botanical history.

The Canadian coast south of the Gulf of St. Lawrence was denuded by the fall of 1932, and when the ice cleared away in the spring of 1933 practically the entire area of the plant's regular range, which extends to the Strait of Belle Isle, was fully 99 percent devastated.

Along the eastern coast of the United States, however, there are still a few tidal estuaries and river mouths not yet seriously affected. One area in Chesapeake Bay (Long Beach) has been under observation for some time, and though as late as June 1933 it had a normal crop of eelgrass, at the end of September not more than 1 percent of the normal crop remained.

Most of the European coast from the Mediterranean to Sweden is known to be similarly affected. The disease appeared first along the French coast during the winter of 1931-32 and spread rapidly. A report from Sweden indicates that the southern coast appeared to be unaffected late in the fall of 1932, but by January 1933 the eelgrass was largely gone.

Eelgrass on the western coast of the United States has not yet been attacked. Species of closely related plants appear to be unaffected. While the cause of the disaster is not positively known, evidence points strongly to a bacterial infection.

Will the Plant Return?

Only time can tell whether the plant will return to its normal abundance. Many areas that at one time showed healthy seedling growth were laid waste a few weeks later. Other areas have shown a progressive improvement since the first widespread destruction. Particularly has this been true in the southern part of the eelgrass range, as in Swanquarter, N.C., and Shinnecock Bay, N.J.

There is a wide difference of opinion regarding the past fluctuations of the eelgrass. All information, however, points to the fact that in the memory of man though there have been periods of scarcity, none has been at all comparable with the present one. Many fishermen and coastal sportsmen assert that there has always been a good crop of eelgrass, while others equally reliable maintain that the plant has fluctuated in abundance.

The importance of eelgrass shows clearly that continued study of the problem of its disappearance is needed. In the meantime protection should be given where possible to those forms of wild life most severely affected. Effort should be made to restore an ecologic balance by attempting to substitute other desirable aquatic vegetation. It would seem that the related forms *Zostera nana* and species of *Phyllospadix* in the more salt waters, and widgeongrass (*Ruppia maritima*) in those less salt, might be used to make good the food and cover lost to waterfowl in the eelgrass catastrophe.

CLARENCE COTTAM, *Bureau of Biological Survey.*

EGGs Oiled by Vacuum Carbon Dioxide Method Keep Well in Storage

The oil treatment of shell eggs as a means of retarding deterioration during storage has received considerable attention during recent years. As a result of work done in this field the vacuum carbon dioxide method for oil treating shell eggs was developed in the Bureau of Chemistry and Soils. According to this method the eggs are placed in a chamber capable of being sealed hermetically which contains a quantity of oil. The air is drawn out until the desired vacuum is obtained; the eggs are immersed in the oil and raised above the surface; and the vacuum is then released with carbon dioxide from a pressure tank.

Studies carried out with eggs given the vacuum carbon dioxide treatment have shown conclusively that this treatment is efficient in maintaining the original quality of eggs during storage.

Oiling Retards Loss of Carbon Dioxide

One of the most important deteriorative changes that normally take place in shell eggs during storage is the development of thin or watery whites. It has been shown that this change is partly caused by the continual loss of carbon dioxide, which subsequently results in an increase in alkalinity of the egg white. A study was made to determine the rate of loss and the average amount of carbon dioxide given off by shell eggs under commercial egg-storage conditions, as compared with the loss of carbon dioxide from eggs that had been oiled before being stored. The eggs used in this work were uniform in size and were graded as U.S. Specials. The study was continued for 1,000 hours. It was found that strictly fresh eggs placed immediately in gas-collecting chambers made for the purpose lost on an average 10 milligrams of carbon dioxide per egg per 24 hours during the first 48 to 96 hours. After that time the amount decreased to about 5 milligrams per 24 hours. Oiled eggs showed an average loss of 5.5 milligrams of carbon dioxide per 24 hours for about 96 hours, after which the amount diminished to approximately 3 milligrams per egg per 24 hours. It is evident, therefore, that oil protection retards the rate of loss and consequently the amount of carbon dioxide lost. Thus it also retards hydrogen-ion change and the formation of thin or "watery whites."

A few unoled eggs that had been held in the same commercial storage room continuously for 2 years were studied in a similar manner. It was found that these eggs, despite their age, still gave off measurable amounts of carbon dioxide in 24 hours, the average being between 1 and 2 milligrams per egg.

Studies on hydrogen-ion concentration in (1) unoled, (2) plain oiled, and (3) vacuum carbon dioxide oiled eggs under storage showed that the vacuum carbon dioxide method exerts a stabilizing influence on the hydrogen-ion concentration. Fresh egg white showed an average pH of 7.6; whites of eggs which had been treated by the vacuum carbon dioxide method and then stored for 8 months showed an average pH of 7.8; plain oiled eggs stored at the same time showed an average pH of 8.3; whereas unoled eggs, similarly stored, showed an average pH of 8.9.

Oiling Does Not Affect Flavor

The grading of shell eggs by candling alone is not a conclusive criterion upon which egg quality can be based. Storage eggs may be graded as high quality when viewed in front of the candle, but may

still possess objectionable flavors. Conversely, deteriorative changes during storage, resulting in low grading before the candle, are not necessarily accompanied by "off" flavor of the egg. Taste tests made on eggs that had been vacuum-treated before storage with colorless, tasteless, and odorless mineral oils of different base and of widely different specific gravities and "pour points" showed that the eggs had retained their original flavor during storage.

T. L. SWENSON and L. H. JAMES,
Bureau of Chemistry and Soils.

EGG Quality, Controlled by Breeding and Feeding, Increases Poultry Income

A coordinated program of research on factors affecting the production of high-quality eggs is being carried on at the United States Animal Husbandry Experiment Farm, Beltsville, Md. Results obtained thus far, together with observations of the commercial handling of eggs, indicate several means by which farmers and poultrymen may obtain better returns from egg production. Consumers have always shown a preference for eggs free from objectionable odors, bad flavors, or discolored yolks. In recent years many consumers have become exacting with respect to other characteristics in eggs and have been willing to pay a premium for eggs of good size, uniform yolk color, and firm whites.

The quality of eggs, of course, is often materially affected by the conditions under which they are held on the farm and by those under which they are marketed. Improved methods of storing and marketing eggs will do much toward maintaining the quality which the eggs possess when they are laid, but the best methods of sanitation and marketing can do no more than maintain the quality of eggs determined by the feeding and the breeding of the birds which produced those eggs.

Eggs of good quality should be clean and fresh, weigh about 24 ounces to the dozen, be uniform in size and shape, have strong shells of uniform color, have firm whites, small air cells, and well-centered spherical yolks of uniform color, not too dark nor too pale. Such eggs command a price several cents a dozen higher than eggs lacking one or more of these qualities.

Shell Color Influenced by Breeding

Scientific studies have shown that shell color is determined by inherited factors and that uniform shell color may be attained only through selection and breeding. Shell quality, including strength and texture, probably may be improved in the same way. It may also be improved through proper feeding. Laying fowls should receive a diet in which the calcium-phosphorus ratio is between 1.8 to 1 and 3.5 to 1. The absolute calcium content may vary from 1.8 to 4 percent, depending on the egg production. The phosphorus content may vary from about 0.5 to 1.2 percent.

Confined layers should always receive from 0.5 to 2.0 percent of the diet in the form of tested cod-liver oil or its equivalent in some other source of vitamin D. Layers, particularly in sections north of the Gulf States, should receive an adequate vitamin D supplement to the diet during the winter months. There is some evidence that bluegrass range contains some factor other than vitamin D which improves shell quality.

Guide to Culling for Egg Size

Egg size is determined in part by inherited factors. Within a breed or strain the larger birds tend to lay the larger eggs; therefore, culling the smaller pullets among those of the same age will improve egg size. A pullet's first 10 eggs should average about 1.75 ounces each if that pullet is to average 2-ounce eggs in her pullet year. Pullets whose first 10 eggs are distinctly lighter than 1.75 ounces each should be culled. Egg size may be increased among confined birds by increasing the protein content of the diet up to about 20 percent, especially if milk products are used.

Quality of Egg White Is Inherited

The quality of egg white is determined largely by inherited factors. There is no experimental evidence that diet plays any part in determining the relative quantity of thick white in an egg. The whites, thick and thin, of a pullet's first egg are somewhat firmer than the whites of the eggs she lays later. This is due to the fact that her eggs increase in weight, owing chiefly to increase in weight of the yolk and the thin white, whereas the weight of the thick white increases relatively little. There is no correlation, however, between firmness of white and egg size among eggs from birds of the same age. The change described is independent of diet and number of eggs laid. There may be diets so poor that they cause watery whites, but this has not yet been demonstrated. Present information suggests the desirability of selecting as breeders those birds which lay eggs with firm whites and whose daughters also lay eggs with firm whites, and likewise the progeny of such birds.

Yolk Color and Quality

Weak, flaccid yolks are found in eggs with watery whites. Yolk color is characteristic of individual birds on a particular diet, and the capacity to transmit pigment may be inherited. Colorless yolks will be produced by any bird, regardless of her ancestry, if the diet is devoid of xanthophyll pigments. These pigments occur in yellow corn, greens, and alfalfa-leaf meal.

Pale yolks of a relatively uniform color may be produced by confining the birds and feeding an all-mash diet which contains limited quantities of yellow corn and alfalfa-leaf meal or other sources of pigment. Barley or white corn may be substituted for a part of the yellow corn. Great care must be taken to supply cod-liver oil to such birds or they will suffer from vitamin A deficiency. The eggs also will be deficient in this vitamin unless cod-liver oil is given, and poor hatchability will result. Some control over yolk color may be attained by feeding a diet containing only a little pigment and permitting the birds to have access to a green range for a limited time each day. Spotted and greenish-brown yolks are likely to be produced if large quantities of cottonseed meal are fed.

Nutritive Value

Although the nutritive value of an egg should be a factor in determining quality, it is usually ignored. Pullets' first eggs contain relatively more protein and water and less fat than their later eggs and the eggs of hens because the yolks of pullets' first eggs are smaller, both in abso-

lute size and in relation to the size of the whole egg. Among eggs from birds of the same age, the larger eggs contain relatively more protein and water and relatively less fat than do the smaller eggs.

The content of vitamins A, B, C, and E in eggs is determined by the diet of the hen. Eggs produced by birds whose diet contains feeds adequate in vitamins A and D may be of therapeutic value on account of containing these factors.

MORLEY A. JULL and THEODORE C. BYERLY,
Bureau of Animal Industry.

EMERGENCY Conservation Work Program Provides Useful and Healthful Work

On the last day of March 1933, President Roosevelt signed a bill enacted by Congress which authorized a vast program for unemployment relief through the performance of useful work in the forests. Under this authorization, some 300,000 men from the ranks of the unemployed have been given healthful outdoor employment in the forests.

In recommending this step President Roosevelt decided upon work in the forests as the first form of employment in his relief program largely because of the unusual opportunities it offers to men from all walks of life to take a fresh start in a healthful occupation in the open. While the work accomplished is much needed and will be largely self-liquidating, the primary object of the plan was to put men to work promptly. The President's message to Congress said in part:

* * * more important, however, than the material gains will be the moral and spiritual value of such work. The overwhelming majority of men who are walking the streets and receiving private or public relief, would infinitely prefer to work. We can take a vast army of these unemployed out into healthful surroundings. We can eliminate to some extent at least the threat that enforced idleness brings to spiritual and moral stability. It is not a panacea for all the unemployment, but it is an essential step in this emergency.

At the same time that unemployment is being relieved, the program will result in the accomplishment of some enormously important public work—work much needed for the protection and improvement of the country's forests. It will be work needed for developing and safeguarding a vital national resource, building for future national wealth. While the purpose of this big forest-work program was primarily unemployment relief, it by no means called for "made work", intended merely to keep men busy. The labor performed in the forests will render a great public service by helping to put the forests of the country in a productive condition which it would have taken decades to attain under ordinary circumstances. It will help to check the huge losses now sustained each year from fires and from floods. It is work that should eventually yield direct and indirect benefits to the Nation far beyond its present cost.

Four Federal Departments Cooperating

Four departments of the Government cooperated in carrying out the project—the Departments of Labor, War, Interior, and Agriculture. A Director of Emergency Conservation Work was appointed by the President to coordinate the whole program. Men who applied for admission to the camps were enrolled by the Department of Labor. in

cooperation with Federal and State employment services and welfare agencies. The War Department conveyed the men from the places of selection to nearby conditioning camps and had general supervision of the work camps. The Departments of Interior and Agriculture have laid out and supervised the work of the organized crews on the national forests, the national parks, migratory-bird refuges, the forests on Indian reservations, and on other federally owned lands.

Much of the work has been done on the national forests, under the jurisdiction of the Forest Service of the Department of Agriculture. The national forests, with a total area of more than 161 million acres, located in 30 States, offer unlimited opportunities for useful work. All of this work on the national forests is in line with an established, long-term improvement program. Fire hazards will be reduced on areas where the greatest danger of fire exists. Timber stands will be improved by thinning and other cultural practices that make for better, faster-growing trees. More efficient fire suppression will be attained through the construction of fire breaks, telephone lines, lookout stations, fire-protection roads and trails, and emergency landing fields. Insect pests and diseases of the forest trees will be eradicated and trees will be planted on burned-over and denuded areas, though the amount of tree planting that can be done is limited by the amount of nursery stock available for planting. It should perhaps be made clear that, while the forest-work program has been spoken of frequently as a reforestation program, reforestation, in the narrow sense of tree planting, is only one of the many lines of work that can be undertaken to promote the conservation and development of our national-forest resources, and the improvement of the national-forest facilities for the benefit of the public.

All this work on the national forests will be in line with existing long-term plans for the development and protection of the forest resources. The plan has meant a vast speeding-up of an established national-forest improvement program.

The act of Congress which authorized the forest-work plan provided also for extending the work to State-owned and private forest lands under cooperative agreements. Congress made the provision in the act for the extension of the work to private lands in order that a larger share of the work might be carried on in the States east of the Mississippi River, where only relatively small areas of Federal and State forest lands exist. Work under this program on privately owned lands involves only such types of projects as are primarily of public benefit, rather than chiefly of benefit to the owners of the land. This includes such things as the prevention and control of forest fires, the eradication of insect pests and tree diseases, the control of floods and checking of soil erosion, all of which work is of direct public interest, and the value of which extends far beyond the boundaries of a given tract of land. The Federal Government was already authorized by Congress to cooperate with the States and private landowners in carrying on work of this kind.

Previous Relief Camps

Forest-work relief camps were not entirely a new experiment. They had been operated with great success recently in California, Colorado, the Lake States, New England, New York, Pennsylvania, and other States. Many such camps, operating in the national forests under the supervision of the United States Forest Service in cooperation with

States, municipalities, and private charities, had furnished forest work to men who were given subsistence by these agencies for themselves and in many cases additional subsistence for their dependents.

In the Emergency Conservation Work program, the Nation's forest resources have been called upon as a means of prompt, effective, large-scale relief for unemployment. The program has had a double purpose—to build forests and to build men. It has given thousands of young men a chance to face the world with a new purpose; at the same time it has improved our forest resources.

CHARLES E. RANDALL. *Forest Service.*

FARM and Nursery Products Move Long Distances Under Japanese-Beetle Certification

The wide extent of territory to which articles restricted under the Japanese-beetle quarantine regulations are shipped each year shows that the regulations do not prevent or seriously interfere with the interstate movement of nursery stock and farm products.

According to the 1930 census figures 1,654 nurseries and 6,436 establishments growing flowers and vegetables under glass, or flowers in the open, were reported as being located in States now wholly or partly under quarantine for this pest. All such establishments located in infested territory are potential shippers of plant material likely to harbor beetle infestation. Returns by these establishments submitted to the Census Bureau show that their lands and equipment were valued at over \$130,000,000. Reported receipts from the sale of products aggregated \$72,000,000. Among these nursery and greenhouse establishments nearly 2,400 handle their products in such a way that freedom from Japanese-beetle infestation can be assured. These firms market their products, at least in part, in uninfested territory. Many of them do a Nation-wide business. Their beetle-free stock is eligible for shipment under a Federal certificate showing compliance with the requirements of the quarantine. Thus certified, nursery and greenhouse products may be moved legally in interstate commerce under the same provisions as similar material originating in uninfested States. As long as a Federal quarantine is maintained, material produced in an infested zone but certified as complying with the quarantine regulations is eligible for interstate transportation to noninfested States without discrimination.

Nursery stock with soil, the commodity in which grubs of the Japanese beetle are believed to have arrived in this country, continues to be the medium which offers the greatest possibility for long-distance spread of the pest. Sand or soil in bulk, or any plant life accompanied by soil, such as potted plants, or grass sod, are equally dangerous carriers of the insect in its larval stage.

No Single Treatment Always Effective

There is no single method of plant culture or chemical treatment which may be practiced to rid all plant material of possible infestation. It is practicable to ship some plants free from soil. Field-grown nursery stock of many species may be assured freedom from infestation by the application of lead arsenate to the soil in the plot. Applied at the rate of 1,500 pounds per acre, the poison kills the Japanese-

beetle grubs living in it without affecting the growth of most kinds of outdoor-grown stock. Plants which cannot be treated successfully in this manner are fumigated with carbon disulphide or naphthalene. Other plants may best be sterilized by hot-water treatment. Plants particularly susceptible to injury by chemical or thermal treatment may be grown in screened greenhouses or beetle-proof enclosures. Hydrangeas have proved to be the most difficult plant species to produce under certified conditions, yet these have been successfully grown in screened enclosures. Thus, methods are available for freeing all types of plant material from beetle infestation or of preventing exposure to such infestation. While some of these policies add to the production cost, it has been the experience of infested establishments generally that the procedure necessary to conform to quarantine re-

FIGURE 40.—Certified nursery stock ready for shipment to uninfested areas.

quirements does not constitute a burdensome handicap affecting their ability to compete with producers in nonquarantined States.

Of the quarantined material shipped under certification, only stock moved from premises exposed to Japanese-beetle infestation is itemized as to individual contents of a shipment. Records are not kept of the number of plants shipped from premises located in the regulated areas but found to be uninfested.

During the fiscal year 1933 quarantined articles were shipped under certification to every State in the Union and to many foreign countries (see fig. 40). The largest quantity shipped from infested establishments to a nonquarantined State consisted of approximately 1,150,000 plants destined for Ohio. Georgia received 875,000 items of nursery and greenhouse stock, and approximately 750,000 plants were consigned to points in each of the following States: Texas, North Carolina, and Virginia. Illinois and South Carolina each received approximately 500,000 plants. States which received between 250,000 and 500,000 plants each were West Virginia, Michigan, Florida, and Alabama. Shipments to Maine, Tennessee, Indiana, Oregon, California, Iowa, Missouri, Wisconsin, Louisiana, and Vermont ranged from 100,000 to

175,000 plants. Certified shipments amounting to between 50,000 and 100,000 plants moved to each of the States of Kentucky, New Hampshire, Minnesota, Oklahoma, and Nebraska. The remaining non-quarantined States received fewer than 50,000 plants each. A total of 2,650 plants shipped to Wyoming was the smallest quantity distributed to an individual State. Shipments under certification to Canada, Cuba, Hawaii, Puerto Rico, and Alaska totaled 120,000 plants.

Geographically, the largest quantity of plants was certified for movement to the South Atlantic States, in excess of 3,500,000 items of plant material having been shipped to those States. The East North Central States received the next largest number, totaling in excess of 2,300,000 plants. Nonregulated territory in the New England States received almost 1,500,000 certified plants. West South Central States were destination points for nearly 1,000,000 plants, while the East South Central States received over 600,000. Consignees in the West North Central States received about 500,000 plants. Approximately 350,000 plants moved to the Pacific States during the year. Of the geographic divisions of the country, the Mountain States received the smallest number of certified plants, about 85,000 being sent under certification to these nine Western States.

Value of Sales of Restricted Products

Restricted nursery and greenhouse products certified for movement from infested establishments during the fiscal year 1933 had a retail value of nearly \$11,000,000. Comparing this amount with the census figures as to the total value of such products, it appears that plant growers in quarantined sections derived approximately 15 percent of their income from sales to nonregulated sections. Shipments to uninfested sections of the country thus furnish an important outlet for plant material grown in quarantined zones under beetle-free conditions. Were the horticultural trade in infested States to be deprived of even a portion of its Nation-wide market, such restraint might seriously affect its margin of profit.

FIGURE 41.—Sand exposed to infestation is fumigated with carbon disulphide before being moved under certification to nonquarantined States. During the flight of the adult Japanese beetle this material must be loaded in closed cars before being fumigated.

Sand, soil, earth, and peat may be shipped under certification if, in mining or digging, the upper 12 inches of surface soil are removed, or if the material is protected from infestation in certain other ways, but if not it must be fumigated or sterilized (see fig. 41). Sand and soil to the extent of 3,809 carloads were certified for movement into 23 nonquarantined States last year. Over 500 certified carloads were admitted to Canada, the Canadian plant-pest authorities accepting Japanese-beetle certification in the same manner as do the uninfested States in this country. Of the nonquarantined States for which this material was destined, Illinois led with 639 carloads. Other uninfested States receiving large quantities of these natural products were West Virginia, 293 carloads; Ohio, 265 carloads; California, 185

FIGURE 42.—Fumigating a carload of bananas with hydrocyanic acid gas to destroy Japanese beetles.

carloads; Kentucky, 158 carloads; and Michigan, 119 carloads. Eighty-three carloads of peat were shipped under certification to nonregulated territory in 14 States. California and Ohio each received 11 carloads.

Adult beetles may infest certain fruits and vegetables when the produce is harvested, or the insects may crawl into the produce in an infested market. So far as possible, certification is granted for vegetables and fruits on the basis of an inspection of the fields or orchards in which the articles are grown, or upon approval of the conditions under which they are packed or graded. In the absence of infestation at the source, containers of quarantined fruits and vegetables are certified without actual handling of the products. Most shipments from an unknown source and most of those produced on an infested farm must be individually inspected. String or lima beans may be run through a mechanical beetle separator. This separator has proved more effective than visual inspection in removing any adult beetles present. Fumigation with carbon disulphide is practiced with raspberries, blackberries, and blueberries. When required, carloads of bananas are fumigated with hydrocyanic acid gas (see fig. 42).

Fruits and vegetables subject to regulatory measures were shipped under certification to all the principal mid-western markets and to

many Southern and Western market centers. Certificates were granted, covering 3,629,434 packages of produce, having an estimated value of \$3,400,000.

Quarantined fruits and vegetables among ships' stores on vessels sailing from regulated ports to noninfested ports in this country also are certified. Inspected produce was used to provision steamships destined for most of the Atlantic and Gulf coastal ports and for the principal Pacific coast ports of call.

Lima and String Beans Most Infested

Lima and string beans were the most heavily infested of the farm products offered for certification. Drought conditions during June in Mid-Western States resulted in an exceptional demand in distant markets for beans grown in southern New Jersey, eastern Pennsylvania, and the Baltimore section of Maryland. Advantageous prices for beans in St. Louis, Chicago, Detroit, Indianapolis, Cleveland, and Cincinnati occasioned an unprecedented demand for inspection and certification of these commodities. This unusual demand was met, and the bean growers were able to realize substantial profits over the prices they would have obtained at markets within the infested zone.

While discharging its obligation to prevent the spread of the Japanese beetle to uninfested States, the Department has not neglected its duty of providing growers in infested sections with ready means whereby they may market their products unhampered by unnecessary restrictions.

L. H. WORTHLEY, *Bureau of Plant Quarantine.*

FARM Structures Last Longer if Given a Preservative Treatment

Decay of wood takes a heavy toll from the farmer. It works silently, and its presence is unnoticed until the damage is done. Rotting fences, buildings, poles, vine stakes, culverts, and the like increase the cost of farming and the amount of unproductive labor the farmer must put in to keep his structures in repair. Much of this expense and labor can be avoided by the proper use of wood-preserving chemicals, which make the wood poisonous to the fungus organisms that cause decay.

If it were possible to keep the wood entirely away from the ground and in a dry condition, it would not decay; but much of the wood used on farms must be in contact with the ground in order to serve its purpose. The heartwood of some woods that are highly resistant to decay will last a long time, even under the most unfavorable conditions. Farmers who have a plentiful and cheap supply of black locust, Osage-orange, southern cypress, cedar, redwood, or chestnut are fortunate, for these woods are highly resistant to decay. Those who must use woods of low or only moderate durability must either make repairs more frequently or must use some artificial method of making the wood last longer.

Good, sturdy heartwood posts of Osage-orange or black locust may last a lifetime. The other durable woods named may last anywhere from 10 to 25 years. In many localities, however, the only posts readily available or cheap are pines, firs, spruces, aspen, cottonwood, and various other nondurable species, which may last only 1 to 5 years.

Fences supported by such posts are likely to need extensive repairs every year. Thorough preservative treatment with coal-tar creosote will make posts of any of these last longer than untreated cedar (fig. 43). A 20-year life can readily be obtained if the treatment is sufficiently thorough.

The small portable hog houses and chicken houses that are used on so many modern farms are quickly damaged by decay. Their life may be greatly extended, however, by treatment with coal-tar creosote. Best results will be obtained by cutting all the boards to finished dimensions and treating them before they are assembled. Cutting lumber after treatment is bad practice, for it exposes the untreated interior of the boards to decay. Creosote is especially suitable for the treatment of animal houses because not only is it effective against decay but it is also discouraging to insect life. A thoroughly creosoted house is a more sanitary place for the animals than an untreated house.

Sidewalks, gates, well curbing, and stable floors are other excellent uses for creosoted wood. The danger of rapid decay in sidewalks and stable floors is obvious. It is not so often recognized that much of the

FIGURE 43.—Preservative treatment would have kept these high-class posts in service many years longer.

difficulty encountered with wooden gates is the result of decay, but close examination of a sagging gate will often show sufficient decay around bolt holes, in joints, or in the supporting posts to cause the trouble.

Creosoted wood is very likely to stain through any light-colored paint applied to it, although aluminum paints are less affected than others. For wood that must retain its natural color or that must be painted, some other preservative than creosote must be used. Zinc chloride solution is the preservative most commonly employed in such cases, although there are several others of similar properties. Zinc chloride is soluble in water and is therefore not suitable for wood that is to be used where the preservative can wash out in a few years. It is very suitable, however, for locations where the wood is merely damp or is seldom thoroughly wet.

Treating Methods

Brush application is the simplest method of applying preservatives but also the least effective. Surface applications of creosote may extend the life of a post for a year or two, but surface applications of zinc chloride solution have little, if any, value. Pressure treating in plants built for the purpose is most effective but not often available to the farmer, and only a few lumber yards carry pressure-treated posts and lumber. It is usually necessary, therefore, for the farmer to do his own treating. This can be done effectively by the open-tank hot-and-cold-bath process, in which the wood is heated in the preservative for 2 to 6

hours and then allowed to cool for 4 to 8 hours, or preferably overnight. The details of tanks and of the treating process are given in United States Department of Agriculture Farmers' Bulletin 744, *The Preservative Treatment of Farm Timber*. Next to pressure treatment, hot-and-cold-bath treatment is best. It has thoroughly demonstrated its effectiveness during the last 25 years, and when properly done gives reliable results.

GEO. M. HUNT, *Forest Service*.

FARM Woods Afford Poor Forage and Deteriorate Rapidly When Overgrazed Pasture land in the Corn Belt has been greatly reduced in area because a large percentage of the available land has been devoted to raising grain

and forage crops, most of which are fed on the farm. Because it is more profitable to feed the grain than to ship it, the livestock industry has become of major importance in the region. Frequently, however, the only pasture land available is that afforded by the farm woods.

It has been estimated that in the better agricultural sections of the Corn Belt there is less than 1.8 acres of pasture land per cow unit. Assuming a 6-month grazing period, this indicates a stocking of nearly twice the computed carrying capacity for good bluegrass pastures. Serious overgrazing is evident; in fact, many farmers report that their native pastures are incapable of supporting half the livestock they formerly did. The wooded pastures, amounting in many counties to more than 35 percent of the pasture land, are even more seriously injured.

Continued grazing of woodland has a disastrous effect not only upon grass cover but also upon tree growth and regeneration. As a result of long-continued overgrazing in the Corn Belt, fully 50 percent of the farm woods are no longer capable of yielding forest products, and the majority are threatened with almost total extinction. The death or the removal of mature trees, combined with the absence of young growth, is gradually converting these areas into open pastures. The most intensively cultivated agricultural sections are faced with practically complete denudation of forest.

There are many economic, agricultural, and sociological reasons for the preservation of the remaining area of farm woods in these sections, if not for their extension; and any comprehensive forestry program for the Central States must include the permanent solution of the grazing problem. One of the first steps in this direction is to determine whether the farm woods of the Corn Belt are capable of furnishing any material amount of forage under the conditions of very heavy overstocking which prevail throughout the region.

Grazing-Capacity Tests

In 1931 a 3-year study was initiated by the Central States Forest Experiment Station and the Purdue Agricultural Experiment Station to determine the actual carrying capacity of farm woods in terms of forage acres. A rather open oak-hickory woodland located on the Pinney-Purdue Farm near Valparaiso, Ind., was divided into three tracts of 18, 12, and 6 acres each. These tracts were fenced off, and three yearling steers were placed in each, thus providing grazing inten-

sities, respectively, of 1, 0.67, and 0.33 acre per head per month for a 6-month season, starting May 1 and terminating October 31. The animals were kept adequately watered and salted, but no supplementary feeding was provided. Weighings were made at biweekly intervals, with extra weighings at critical periods.

During the first season's tests the largest tract, grazed on the basis of 1 acre per steer per month, permitted fairly consistent gains averaging 1 pound per head daily for the first 3 months. This gain, however, was almost entirely lost during the last half of the summer, and when the animals were removed on October 31 they showed an average gain of only 0.17 pound per day. Similarly, on the second tract, grazed on the basis of 0.67 acre per steer per month, fairly consistent gains of 0.8 pound per head per day were maintained until September 1, after which the weights dropped sharply, and the animals showed an average loss of over 30 pounds at the end of the season. The animals in

FIGURE 44.—Livestock in such pastured farm woods soon starve unless given supplementary feeding, and future values in forest products are seriously reduced by this profitless grazing.

the third tract, grazed on the basis of 0.33 acre per steer per month, were unable to make any consistent gains even during the early part of the season, and it became necessary to remove them after 3 months to prevent loss of weight beyond the point of recovery.

As was expected, the results of the second season's tests indicated an even lower carrying capacity for all three tracts. Gains during the early part of the season for the 18-acre and 12-acre tracts were neither as great nor as long maintained as the previous year, and the animals in the 6-acre tract had to be removed on July 15 to prevent starvation. At this writing the third-year tests had not been completed, but the weighings taken indicated a further decline in carrying capacity. The animals in the 6-acre and 12-acre tracts were removed on June 15 and July 25, respectively, to prevent starvation. Even in the 18-acre tract the gains have been small and erratic, and it may be necessary to remove the animals prior to the close of the 6-month season.

The experiment is expected to yield valuable information when it is completed and the data are thoroughly analyzed. It will include not only material on the carrying capacity of farm woods, but also additional evidence on the effect of the various intensities of grazing on the vegetative and tree growth found in the tracts (fig. 44). It is perfectly clear at this time, however, that none of the three intensities of grazing used was sufficient to provide for consistent livestock gains over the entire 6-month grazing season. Observations, supported by the weighings thus far recorded, indicate that in this particular type of farm woods a minimum of 2 acres per head per month would be required to maintain an average daily gain of 1 pound per steer per day. On this basis alone, and without consideration of the effect on the woods itself, the average farm woods is being overgrazed by at least seven times its carrying capacity. It is obvious that under such conditions and without supplementary feeding, the animals would soon starve to death.

RALPH K. DAY, *Forest Service.*

FARM Youth, Lacking City Opportunities, Face Difficult Adjustment

Many people in a large group, peculiarly affected by the economic depression, have been overlooked, despite the fact that they deserve special consideration, for upon them the Nation must depend largely in the future for the maintenance of its strength. These people, almost forgotten because their need is less acute than is that of many urban unemployed, are the young people on the farms who would, under normal conditions, have found work in the cities.

Between 1920 and 1930 the net migration from the farms, mostly to the cities, was about 6,000,000, an average of 600,000 a year. Probably three fourths of these migrants were under 35 years of age. They were not needed on the farms to produce food and fiber, for production of these commodities during the decade prior to this depression was larger than could be sold at a fair price. But in 1930, as work became scarce in the cities, the migration from the farms diminished, while the migration to the farms from the cities increased somewhat, with the result that arrivals on farms exceeded departures by a few thousand. In 1931 the net movement to farms rose to more than 200,000, and in 1932 it was more than 500,000. This increase, however, was the result of the great decline in the migration from the farm to the cities and not the result of an increase in the migration from the cities to the farm. Figures are not yet available for 1933, but the indications point to a decrease in the farmward migration, doubtless in part because those who have relatives and friends on farms who are willing to receive them have nearly all returned.

A large proportion of the unemployed now in cities were born in cities or left the farm many years ago. They are therefore city people with city ways, city hopes, and city inaptitude for farm life. Moreover, these city people are rapidly growing older, and a large proportion are becoming increasingly unfitted for such heavy work as farming. There were 51 percent more people over 65 years of age in the urban population of the Nation in 1930 than in 1920, and the increase during 1930-40 may be fully as great. Simultaneously the number of children in the cities is decreasing rapidly. In 1930 over 8 percent of our population consisted of children under 5 years of age, while only 5 percent

were people over 65 years old. Before 1950 these proportions are likely to be reversed.

On the other hand, the number of young people on farms is increasing. Let us assume that during the next 6 years there will be a slight net movement from the farms back to the cities, but only enough to balance the net movement to farms during the years 1930-33; in other words, that no net migration from farms occurs during the decade 1930-40. In this case, there would be about 2,250,000 more males over 20 years on farms on January 1, 1940, than there were on January 1, 1930; and if the same proportion of these males operate farms as were operating farms in 1930, there would have to be about 1,200,000 more farms in the Nation in 1940 than in 1930. Some allowance must be made, however, for the fact that the men who return to the farms from the cities are older than those who leave the farms for the cities. After this allowance is made, there is indicated a need for more than a million new farms by 1940, on the assumption that there is no net migration of people from farms to cities during the decade 1930-40.

Now, a million new farms would be an increase of nearly one sixth in number of farms. If this development should occur without aid or direction, two things are likely to happen:

(1) Subdivision or joint operation of many farms; if a farmer has 2 sons, instead of 1 going to town, both will now remain on the farm.

(2) Reoccupation of abandoned farms and the clearing of forests from much poor, sandy, or mountain land, for, frequently the birthrate is highest and the population densest where the soils are poor, and there are many ambitious young people in rural regions whose fathers do not own farms. Such extension of crop production onto poor land would mean in many cases increased losses of soil fertility by erosion, increased production of farm products at a time when such products would tend to depress prices, decreased income for farmers, and a declining standard of living.

Three Possibilities Indicated

How are these conditions to be avoided? There appear to be three major possibilities in the situation:

(1) Employment in the cities may become available for the youth from the farms, with the return of prosperity. But a resumption of this farm-to-city migration will accelerate the decline in the birthrate and hasten the approach of a stationary national population, since these youths who go to the cities will have, in all likelihood, only one half to two thirds as many children as they would have had on the farms.

(2) Decentralization of industry may enable many young people to migrate from the farms to villages and small towns, instead of to the cities. It is even possible that farmers and their families, using modern looms and similar machinery, can produce at home some kinds of manufactured goods for the use of themselves and their neighbors instead of buying these goods at retail in the stores. But whether such decentralization of factories, accompanied, perhaps, by development of home industry, will take place rapidly enough to provide work for the accumulating surplus of young people on the farms is doubtful.

(3) Nearly all the farm youth may become farmers, with the consequences previously noted, unless the Government helps them to find farming opportunities, possibly of a type that will not contribute greatly

to production for sale. These young people have little information as to where it is best to locate, and if they had such information, many of them have so little money that they could not buy good farms, or even rent them, unless they are well known in the neighborhood. Unguided and unaided, some of them will soon be compelled to clear the forest or plow up the prairie sod and bring the land under crop.

The average age of the farmers of the Nation is increasing. In 1910 about 28.9 percent were under 35 years of age; in 1920 this proportion had fallen to 26.9 percent, and in 1930 to 23.4 percent. On the other hand, 23.6 percent of the farmers in 1910 were over 55 years old; in 1920 this proportion had increased to 24.8 percent, and in 1930 to 28.6 percent. Many of these farmers over 55 years of age would like to retire. But since farm youth lack capital, particularly after these 13 years of economic depression, few are able to buy farms. Partly as a consequence of this, city people and institutions appear to be owning an increasing portion of the Nation's farms.

How to facilitate the transfer of land from one generation of farmers to the next is a subject which urgently deserves study and speedy action. It may well be that the Government can perform a very real service in guiding and financing the purchase of farms by capable farm youth. This service not only will benefit these individuals, but also will contribute to the welfare and stability of the State. America has been called the land of opportunity. It must remain a land of opportunity for the youth if it is to continue to be America.

The old people should be encouraged to remain on the land, retaining the old home or building a new one nearby, or on the edge of a neighboring village, for frequently retired farmers fail to find happiness in the cities. Moreover, migration of farm youth as well as of retired farmers to the cities has transferred many billions of rural wealth to urban centers. This is a drain which the rural people should endeavor to diminish.

O. E. BAKER, *Bureau of Agricultural Economics.*

FERTILIZERS May Add to Soil Acidity; Neutral Mixtures Desirable Many of the commercial fertilizer ingredients, especially the nitrogenous materials, as well as the majority of the mixed fertilizers sold during the past few years, have been acid forming. Usually no marked harmful effect from such acidity was observed where such materials were used at moderate rates and for only 1 or 2 seasons. On the other hand, their long-continued use, especially on soils already rather acid and on which liming was not practiced, frequently resulted in a marked increase in acidity, and a consequent lowering of the efficiency of the fertilizers. A growing appreciation of these facts has stimulated the interest of the fertilizer manufacturer and the farmer in the production and use of neutral mixtures.

This brings up the question of what is the residual effect of the different types of fertilizer materials. It is well recognized that the usual sources of potash, such as kainit and sulphate and muriate of potash, have little effect on soil reaction. These materials are not only neutral but undergo no changes in the soil which would appreciably affect the reaction.

The phosphate carriers vary considerably in their effects. Materials such as superphosphate in which the phosphate is present largely as

monocalcium phosphate, have little effect on soil reaction. Di- and tricalcium phosphates exert a basic and not an acidic effect. Ammonium phosphate, however, increases acidity, as do the other common ammonium fertilizer salts, as explained below. The fact that superphosphate, a monocalcium phosphate, produces little effect upon the soil reaction when applied to soils in the humid region, is due primarily to the fact that phosphoric acid is a weak acid and only a partial displacement of its acid ions is necessary in order to produce a material having an acidity corresponding to a pH of 5 to 6, which is common for most soils of this region.

The nitrogen carriers are responsible for most of the fertilizer acidity effects, but not even all of these are acid forming. The nitrate fertilizers, in which the nitrate is combined with sodium, potassium, or calcium, decrease soil acidity because the nitrate ion is absorbed by the plant largely apart from the bases, leaving the latter to exert their full basic action. Cyanamid also exerts a basic effect, because of its content of calcium present both as hydroxide and as cyanamide.

Most of the nitrogenous fertilizers that contain their nitrogen in the form of ammonium salts, such as ammonium sulphate, ammonium chloride, and ammonium phosphate, are very acid producing. Whereas plants may absorb some of the ammonia directly, leaving the mineral acids in the soil, probably most of it is nitrified and taken up by plants as nitrate. The resulting effect on soil acidity is essentially the same in the two cases. If much of the nitrogen is leached out, however, the acidifying effect is greater following nitrification.

There is considerable variation among the organic nitrogenous fertilizers with regard to their effects on soil reaction. If the nitrogen of these materials is wholly taken up by plants, most of them do not increase acidity, and many even exert a slight basic effect, due to the calcium and other basic elements present. Loss of the nitrogen by leaching, after the materials have nitrified, will, however, result in a much greater acidifying effect since bases equivalent to the nitrates formed are then removed. While the effect of each material must be determined separately, it may be stated in a general way that most organic nitrogenous fertilizers, as used under practical conditions, are only slightly, if at all, acid forming.

Leaching is Biggest Variable Factor

An accurate statement as to the exact effect of a given quantity of nitrogenous fertilizer on soil reaction cannot be given because of the wide variations in soil conditions and farming practices. The most variable factor is leaching. If ammonium sulphate, for instance, nitrifies in the soil, an acidity corresponding to both the sulphuric acid and the nitric acid formed, results. This acidity, which would require 150 pounds of calcium carbonate per 100 pounds of ammonium sulphate for neutralization, is all permanent if the nitrates are removed by leaching. On the contrary, if the nitrogen is absorbed by the plants the final acidity corresponds closely to the sulphuric acid added and not to the sulphuric plus the nitric acid, because the plants take up the nitrate nitrogen largely apart from the soil bases. Under field conditions leaching always occurs, and so ammonium sulphate causes an acidity corresponding to all of the sulphuric acid present plus a fraction of the nitric acid formed. Some investigators in considering the manufacture of neutral fertilizers have recommended

that any nitrogen added that is capable of being converted into nitric acid in the soil, such as urea, ammonia, or organic nitrogen, be assumed to have an acidifying effect corresponding to half the nitric acid that may be so formed. In addition, the acidity due to mineral acids present, such as sulphuric in the case of ammonium sulphate, which act as carriers of the nitrogen, would be calculated at full value; likewise, any mineral bases, such as the sodium in sodium nitrate, would be considered as exerting their full neutralizing effect. Fertilizer mixtures, compounded on the basis of these assumptions, should exert no appreciable effect on soil reaction under ordinary conditions of use.

A factor, commonly overlooked, is the effect of the crop itself in increasing soil acidity, wholly apart from the fertilizer used. Analyses of farm crops show that the quantity of mineral bases present is greater than the quantity of mineral acids. The larger the crop, then, the more of the basic materials removed and the more acid the soil becomes. Certain crops, particularly many legumes, are known as calcium-loving, while grain crops remove considerably smaller percentages of excess base. Strictly speaking, it is incorrect to consider this acidity as fertilizer acidity. This is well illustrated by reference to legume crops. A given weight of alfalfa will remove about the same amount of basic materials from the soil whether the nitrogen is supplied in the form of urea, for example, or whether it is obtained from the air by means of nodule bacteria. In this particular illustration if we say that urea produced the acidity in the one case, we must also say that the atmospheric nitrogen produced it in the other. It would seem more logical to attribute the acidity to the crop in both instances. This point need not particularly concern the fertilizer manufacturer, but is of considerable scientific interest and helps to explain why higher acidities than would otherwise be expected are sometimes observed following the use of fertilizers.

While fertilizer acidity is important, and the growing tendency to manufacture neutral mixtures should be encouraged, it should always be borne in mind that in the humid region the natural leaching out of soil bases, mostly in the forms of carbonates and nitrates, is commonly responsible for the larger portion of the increase in soil acidity. The more basic the soil originally the greater is this loss of bases through these natural agencies. Even though neutral fertilizer mixtures are used, these losses will continue and should be compensated for by occasionally liming the soil.

FRANKLIN E. ALLISON,
Bureau of Chemistry and Soils.

FERTILIZER Studies Show Important Possibilities in Ammoniated Peat

Fertilizers as first employed consisted principally of decomposition products from vegetable and animal residues. The effectiveness of such substances in promoting plant growth was due largely to their contained nitrogen. Organic nitrogenous materials of both plant and animal origin have always been employed in the manufacture of mixed fertilizers and until recently have contributed the major portion of the nitrogen used for this purpose. The amount of high-grade materials available for such use has diminished gradually because of

their diversion for feeding purposes; and to obtain them for fertilizer the manufacturer and farmer have been required to pay the high price based on their valuation as feeds.

New developments in the fertilizer industry have also changed the relations of organic materials to mixed fertilizers. The development of nitrogen-fixation processes, with the resultant production of large supplies of nitrogen products at low prices, has been an important factor in reducing the use of organic materials in fertilizers. The change in the constitution of mixed fertilizers is such that in 1931 only 18 percent of the nitrogen was derived from organic sources and 60 percent was derived from ammonia and its compounds, in contrast to 91 percent from organic sources in 1900.

The possibility of establishing an adequate supply of organic nitrogen depends upon the utilization of some abundant source of organic

FIGURE 45.—Small bombs and accessories used in ammoniation of peat.

material as a carrier of the cheap ammonia produced synthetically. Peat is a promising material for use as such a carrier because of its occurrence in large quantities in this country, and its comparative noncommercial value at present. A relatively insignificant amount is utilized, principally as a conditioner in mixed fertilizers and in greenhouse work or other special cultural conditions.

Treating Peat with Ammonia

The nitrogen in natural peat, ranging from 1 to 4 percent, is a potential source of plant food if it can be rendered available. Numerous attempts have been made to accomplish this, but from a commercial viewpoint these have been unsuccessful, either wholly or in part. The object of the work in the Bureau of Chemistry and Soils was not only

to render the original nitrogen available but to enhance the nitrogen content by treatment with ammonia. Peat was treated with liquid anhydrous ammonia, a number of different peats being used and the temperature, pressure, moisture content, and time of treatment being varied to determine the effect on the amount of nitrogen in the treated material (fig. 45). Where higher pressures were involved the peat and ammonia were placed in a steel container, and after being closed, the vessel was heated to the desired temperature. The product contained more nitrogen than before treatment, varying in amount with the imposed conditions. The temperatures employed varied from 50° to 300° C. and the pressures from atmospheric to 300 atmospheres. Different peats yielded products with a nitrogen content of 4 to 6 percent at 50°, 10 to 13 percent at 180°, and 14 to 21 percent at 300°. The greatest increase in nitrogen content occurs during the first few hours of treatment, though there is a gradual increase up to 20 hours. With 10-percent moisture the maximum nitrogen is obtained in the product, but more moisture decreases the nitrogen content. Increase in pressure increases the nitrogen content of the treated peat. The type of peat has some influence on the quantity of ammonia fixed, but the total nitrogen in the product is surprisingly close in different peats treated under similar conditions. No correlation has been observed between the acid or alkaline character of the peats and the amounts of nitrogen added.

Properties of Ammoniated Peat

The nitrogen in ammoniated peat is about one third water soluble and two thirds insoluble. Urea has been found to constitute nearly half of the water-soluble portion. In the insoluble portion the presence of ammonium, amide, and imide nitrogen has been established, but the character of 65 percent of the nitrogen has not been identified. Part of the nitrogen being insoluble indicates that it may supplement more soluble nitrogen compounds and be retained longer in the soil under conditions favoring loss by leaching. If it is found to be available for plant growth it will furnish an organic material that will meet the demand for the present diminishing supply of such fertilizer. Laboratory tests according to the A.O.A.C. methods indicate a high activity for the insoluble nitrogen, but it will be necessary to evaluate it as a fertilizer material from its availability as a plant food as determined through vegetative tests. Such tests are being conducted at several places by different cooperators.

The physical condition of the ammoniated peat indicates that it should be valuable for use in mixed fertilizers as a conditioner, preventing caking of mixtures on storage and causing them to retain a condition suitable for easy distribution in the field. It is a black granular material, apparently dry and easily powdered.

Economic Considerations

Should vegetative tests result favorably, commercial production of ammoniated peat seems promising from the standpoint of the cheapness and abundance of the raw materials. There are estimated by the United States Bureau of Mines to be 13,000,000,000 tons of deposits of peat with potential economic importance in the United States. It is distributed widely from Minnesota to Maine, along the Atlantic and

Gulf coasts from Maine to Mexico, and to some extent in the far West. Nearly half of this vast quantity occurs in Minnesota and 70 percent of the remainder in Michigan, Wisconsin, and Florida. The other raw material, ammonia, is one of the cheapest forms of nitrogen and the most abundant. It is easily shipped as anhydrous liquid in tank cars. In certain locations, such as Florida, where peat and phosphate rock occur close to each other, the preparation of the raw material, the ammoniation and the manufacture of mixed fertilizer might be carried out at the same place and in the immediate vicinity of an intensive fertilizer-consuming area.

R. O. E. DAVIS, *Bureau of Chemistry and Soils.*

FERTILIZERS Without Filler Cost Less and Meet Ordinary Needs

Between 1870 and 1880, when mixed fertilizers came into general use, they had a total plant food content of only 10 to 14 percent. Higher concentrations were commercially impractical then because the only materials available for making them were low in plant food. Such mixtures, in time, became firmly established as fertilizer grades.

During the past 50 years many changes have occurred in the materials used in making complete fertilizers. Some have almost disappeared, as for example poudrette and wood ashes. A large part of the production of other materials like animal tankage, fish scrap, and cottonseed meal, which at one time were used almost exclusively as fertilizers, has been diverted to other uses. At the same time methods of producing fertilizer materials have steadily improved so that the average plant-food contents of many of them have increased. For instance, superphosphate contained on an average 11 percent of available phosphoric acid in 1880 and 18 percent in 1932. The average potash content of kainit increased at the same time from 12.5 to 16 percent. In addition to the changes already mentioned, a number of new processes for making cheaper and better fertilizer materials containing high proportions of plant food have been developed. These changes have forced the industry to adopt one or the other of two courses or a combination of them. Manufacturers have either produced fertilizers of gradually higher analysis or have diluted the higher grade materials with more and more filler to produce the same grades that had already become well established in the trade.

The savings possible by using fertilizers containing 20 percent or more of plant food are not yet fully recognized, and therefore many farmers still buy 2-8-2 and similar 1880-style fertilizers because they have become accustomed to them through long usage. As long as farmers demand this grade of fertilizer, manufacturers will naturally supply them. In North Carolina alone in 1931 a half million tons of fertilizers were sold containing less than 14 percent of plant food calculated as nitrogen, phosphoric oxide, and potash. If no filler has been added to the materials known to have been used in making fertilizers in the country as a whole in 1931, the average complete mixed goods would have contained 21.1 percent of plant food. It actually did contain 17.9 percent. Therefore, 15 percent of all the mixed fertilizer sold in this country during that year consisted of added material which contained no nitrogen, phosphoric acid, or potash. It is also known that some fertilizer mixtures are more than one third filler. It

is impossible to make mixed fertilizers containing less than 14 percent of plant food with the ordinary materials available today without using large quantities of filler.

Some Filler Materials Not Worth the Cost

Some materials containing none of the usual plant foods have some value when added to certain fertilizers, but sand, sawdust, ground cork and coal ashes, all of which are used in large quantities, are not only not worth what they cost, but they increase the cost of the plant food bought and as a rule add nothing of value. Filler costs money. The manufacturer as a rule buys sand for this purpose, but even if it can be excavated from his own land the total cost may run as high as a dollar a ton. When 500 pounds of sand is added to 1,500 pounds of high-grade materials to make a ton of mixed fertilizer the farmer has to pay for this sand, as well as for about 30 cents' worth of extra sacks to hold it, one third more freight from the factory to the dealer, and other extra costs, all of which together increase the retail price from \$3 to \$5 for a ton of this kind of mixture.

The retail selling price of fertilizers is recorded in some States at the time inspectors gather samples for analysis in the control laboratory. These published prices and the corresponding analyses have been averaged by grades to determine the cost of a pound of each plant food when bought in various grades. It was found that in every State and every year the average cost per pound always decreased as the concentration of the fertilizer increased. The decrease in cost was always rapid until the plant-food content reached 18 or 20 percent, above which the decrease continued, but was usually slight. For example, the same number of pounds of plant food on an average cost about 20 percent more when 2-8-2 is bought instead of 3-12-3 fertilizer. By purchasing 4-16-4 a further saving of about 5 percent could be made as a rule. In other words, 6 tons of 2-8-2 in 1931 cost on an average about \$144, while 4 tons of 3-12-3 cost \$120, and 3 tons of 4-16-4 cost \$115, but all of these lots contained the same quantities of plant food. Diluting fertilizers with filler is estimated to have cost the farmers of the United States about \$7,000,000 in 1931 alone.

Very concentrated mixtures are sometimes prepared from such highly purified ingredients that they may be deficient in other elements of plant food such as calcium, magnesium, and sulphur, which though sometimes lacking are generally present in satisfactory quantities as impurities in mixtures containing the usual amounts of nitrogen, phosphoric acid, and potash. Mixtures containing 40 percent or more of the principal plant foods may very easily be prepared, however, so as to contain sufficient of these other elements to meet ordinary plant needs. When magnesium or some other element is required, the consumer is justified in paying more to get a mixture containing it, and dolomite and similar materials should not be considered as fillers in the ordinary sense. When the conditions are such that nothing but nitrogen, phosphoric acid, and potash are needed, the most concentrated fertilizer is likely to be the most economical.

In conclusion it should be repeated that large quantities of useless filler greatly increase the cost of fertilizers to the farmer. He has an opportunity to save money by giving more consideration to the cost per pound of plant food than to the cost per ton of fertilizer in making his purchases.

FIRE-CONTROL Roads and Motorway Fire Lines in the Lake States Region

Rehabilitation of the devastated timber lands in the Lake States region, under the provisions of the Clarke-McNary law, is primarily a protection and reforestation problem. Destructive logging methods of the past, followed by repeated fires, have rendered nonproductive millions of acres of the one-time highly productive timber lands in northern Michigan, Minnesota, and Wisconsin. Under present conditions the speculative value of these lands is not sufficient to justify the annual carrying charge, or to warrant their retention in private ownership.

Out of this vast area of denuded lands several demonstrational forest units have been created by the National Forest Reservation Commission. The reclamation of these lands under intensive forest management, in order to demonstrate the timber-growing possibilities of the region and to encourage the practice of forestry and the retention of the

lands in private ownership for timber production, is the major objective of the Forest Service in the reforestation program now under way.

These areas are largely of the sand-plains type, wherein destructive cutting, followed by numerous fires, has caused a conversion to grass and brush types of extremely high fire hazard. To overcome

FIGURE 46.—Standard double firebreak, Huron National Forest.

the fire menace and reduce the fire risk to a minimum, a transportation system of protection roads and motorway fire lines is being developed, together with a plan for the placement of firemen at strategic points, so that it will be possible to reach any portion of a given area within a safe allowable elapsed time after a fire is reported.

For the protection of plantations and such limited areas as support natural reproduction of jack and Norway pine, a system of motorway fire lines is being provided to facilitate fire suppression as an added insurance against loss by fire. This development is restricted, however, to the sand-plains areas of extremely high fire hazard, and the fire lines are so located as to block out areas of approximately 1 square mile. The fire lines consist of two graded strips, each 8 feet wide, having a 12-foot strip between them, which is cleared and otherwise developed to a low-standard motorway, suitable for truck travel at speeds of 10 to 15 miles per hour. The fire-line strips are so graded as to expose the mineral soil and are kept free of vegetation, leaves, and other accumulations of inflammable material by disking. They are designed to serve the dual purpose of a place to make a stand against an approaching fire, by back-firing or otherwise, and a low-speed road for the transportation of men, water, and other fire-fighting equipment.

The construction work is performed with caterpillar-type tractors and graders. Except to remove large stumps, very little blasting, clearing, or other hand work is required (fig. 46).

Some 300 miles of motorway fire lines have been constructed at an average cost of \$158 per mile. A total of 1,100 miles, estimated to cost \$165,000, is planned for the protection of the existing and proposed planting areas within the several forest units now under Forest Service administration.

Maintenance work is done on the fire-line strips once or twice each season, with a light track-type tractor and a tandem disk, at an average cost of \$1 per mile of double line, per maintenance operation (fig. 47).

FIGURE 47.—Fire-line maintenance with tractor and disk.

The motorway fire-line system is being further supplemented with a sufficient mileage of somewhat higher speed protection roads to afford rapid transportation of fire crews and fire-fighting equipment. Such roads are suitable for light-car travel at speeds of 20 to 30 miles per

FIGURE 48.—Newly constructed protection road widened for fire control.

hour and truck speeds of 15 to 25 miles per hour. Within the areas of high fire hazard and risk these roads are turnpiked to a 26-foot width, and are kept clean of vegetation by grader maintenance, to insure their usefulness as a firebreak. During 1931, 160 miles of road of this type were improved or constructed to this standard at an average cost of \$320 per mile (fig. 48).

H. COLEMAN, *Forest Service.*

FIRE Wounds Have Close Relation to Exterior Discoloration of Bark

Fires in the hardwood forests of the southern Appalachian region seriously affect the health and vigor of the trees. Ground litter may be destroyed, seedlings and young trees may be consumed, and even the largest trees may be killed.

While such severe fires are the exception, even a moderate fire is very destructive. Intense heat from the burning litter kills the tender living tissues of the inner bark. These wounds interfere with normal sap movement and provide entrances for wood-rotting fungi.

To determine the possible relationship between exterior bark discoloration and wounds caused by the death of the inner living bark, a

FIGURE 49.—A, Charred and scorched areas on white oak 11.4 inches in diameter breast high; B, the same tree with the bark removed to show the basal wound caused by fire.

cooperative study of basal fire wounds was made by the Appalachian Forest Experiment Station and the Division of Forest Pathology of the United States Department of Agriculture. Three hundred and fifty trees of white, black, chestnut, and scarlet oaks and yellow poplar, varying in diameter from 4 to 28 inches breast high, were examined. These trees had no crown damage or abnormalities other than a discolored area of bark caused by fire. By dividing the discolored areas into arbitrarily established classes—scorch, char, and burn—an attempt was made to classify the intensity of heat to which each tree had been subjected. The areas of external discoloration and internal wound were carefully measured, and the correlation between these areas and tree diameter was determined. Subsequent analysis of the data showed that predictions of the size of wound based on careful measurement of these classes of discoloration were only slightly more accurate than those based on total discoloration (fig. 49).

Resistance of Different Species

Of the five species examined, yellow poplar, one of the most valuable species in the southern Appalachians, was most resistant; chestnut, white, and black oaks were intermediate; and scarlet oak, considered one of the less valuable oaks, was most susceptible. There was a fairly high correlation between the area of discoloration and the area of wound for all but scarlet oak, which is so susceptible that the inner bark had been killed sometimes for 20 feet above the highest point of discoloration. Graphs prepared by statistical methods for each species show by diameter classes the relation between discoloration and wound. Taking trees with a diameter of 10 inches breast high as examples, a fire which causes 5 square feet of discoloration on the outer bark should produce on an average $1\frac{1}{2}$ square feet of wound on yellow poplar, 3 square feet on chestnut oak, 4 square feet on white oak, $4\frac{1}{2}$ square feet on black oak, and $7\frac{1}{2}$ square feet on scarlet oak.

The relative order of resistance of the three intermediate species depends upon the diameter of the particular tree and area of discoloration which is selected as the basis of comparison. Scarlet oak, however,

FIGURE 50. —A, Areas of discoloration, burned, charred, and scorched on a black oak (117) and a scarlet oak (118), both 13 inches diameter, breast high; B, bark removed to show extent of basal wound associated with discolorations. Horizontal chalk marks are applied at 1-foot intervals.

always remains the most susceptible, and yellow poplar the most resistant, regardless of the size of the discoloration or the diameter of the tree.

The insulating properties of the bark influence the relative resistance of various species of trees. Within a species the tree with the thickest bark is afforded the best protection. Other factors such as bark character and structure are also of significance. Measurements of bark thickness made at 6 inches aboveground indicate that chestnut oak and yellow poplar have the thickest bark, scarlet and black oaks are intermediate, and white oak has the thinnest bark. Yellow poplar has

an extremely thick layer of moist inner bark which makes for good insulation. White oak bark is soft and flaky, whereas black and chestnut oak bark is hard and firm. The bark of scarlet oak is comparatively smooth, and, although equal in thickness to that of more resistant species, apparently is a better conductor of heat (fig. 50).

In addition to growth rate, form, and value of the wood, the relative resistance to basal injury should at present be considered in judging the desirability of a species for timber production in the southern Appalachian Mountains.

I. H. SIMS, *Forest Service*.

FLY Trapping Aids in Combating Screw-worms of Livestock The pernicious activity of the screwworm is one of the most serious problems with which the stockmen of the Southwest have to deal. The losses resulting from the attack of this fly have been estimated at from \$4,000,000 to \$10,000,000 annually. Although its depredations are normally confined to Texas, Arizona, New Mexico, and California, there are occasional outbreaks elsewhere in the southern part of the United States. For instance, during the summer and fall of 1933 an unusual set of conditions gave rise to a serious outbreak, with heavy losses, in northern Florida, southern Georgia, Alabama, and Mississippi. In the territory where this pest occurs all kinds and classes of livestock are attacked, not infrequently deer and other wild life are affected, and even man may fall a victim of its ravages.

The screwworm is the larval or maggot stage of a common species of blowfly, which is bluish green and has a reddish-yellow head and three dark stripes down its back between the wings. The insect likes warm weather and is unable to overwinter in this country except in the extreme southern parts. Screwworms breed in tremendous numbers in carcasses of animals soon after death. Development is very rapid, especially in warm weather, when a generation of flies may be produced in less than a week from the time the eggs are laid. The fly may live many days, and the female may deposit 10 or 12 batches of eggs during its life. When the flies become abundant they turn their attention to living animals. They lay their eggs on blood spots where ticks are crushed, on newly born young, and on wounds of all sorts. The young maggots penetrate the tissue, and soon serious damage is done, which often results in the death of the animal attacked.

How the Trap is Made and Used

In an effort to find means of reducing the heavy losses, many different lines of attack have been studied by the Bureau of Entomology. One of these is the development and use of traps designed to capture and destroy the flies.

Of all the devices thus far tested the cone-type trap has been found most suitable for general use. This trap is about 18 inches in diameter and 24 inches high and is made of screen wire on a metal or wooden frame. For use on the range it is provided with legs about 4½ inches high, which are attached to a rough platform nailed in a tree (fig. 51), where the trap will not be disturbed.

Beneath the trap is placed a bait pan about 14 inches in diameter containing about 2 pounds of meat, usually from cull sheep or goats. The meat is immersed in water (about 2 gallons) to prevent drying, and to each gallon of water 1 teaspoonful of 40 percent nicotine sulphate is added to prevent maggots from developing in the bait. The addition to the water of 1 percent (by weight) of sodium sulphide powder increases the attractiveness of the bait and makes it last longer.

The number of traps that can be used economically on a ranch, their location, and the frequency of renewing baits and emptying the traps are all important considerations, the correct determination of which involves extensive and long-continued experiments. Much light has been shed on these questions by experiments carried out in western Texas during the past 4 years. These tests were conducted on a typical ranch area of about 160,000 acres, and a similar area was used in checking the results. From 1 to 4 traps were used per section. The larger number captured by far the most flies per section. Theoretically, at least, this gives greater protection to livestock.

It has been shown that the type of place chosen for the traps is of great importance in the capture of flies. The largest catches of the screwworm fly were made in traps exposed to the sun, protected from direct wind, and surrounded by timber and undergrowth of medium density.

During the summer of 1932, 8,337 gallons of flies were captured in the trapped area in Texas. A large percentage of these were screwworms.

Benefits Obtained by Trapping Flies

It has been extremely difficult to determine accurately how much benefit may be expected from the operation of flytraps. In the summer of 1932 the trapped area showed a 3.4 percent screwworm infestation in all classes of livestock against a 5.9 percent infestation in the nontrapped area. There was also a 58 percent reduction in the number of flies. The reduction in the number of cases does not, however, indicate all the benefits, as the severity of the cases and the number of reinfestations appear to have been lessened, though these points were not accurately determined. Additional benefits came from the destruction of other kinds of flies, such as flesh flies and blue-bottle flies, that annoy in the household and contaminate carcasses of animals that have been recently butchered.

FIGURE 51.—Trap designed to capture the screwworm fly on ranges.

It should be borne in mind that fly trapping is considered only as a supplemental measure in combating the screwworm. Fly breeding must be cut down as far as possible by prompt burning of carcasses, and conditions favorable to screwworm attack must be reduced by arrangements that will provide for the birth of young and such operations as dehorning, branding, etc., out of fly season, and by preventing injuries to the animals. Regardless of the efforts made to find and destroy all dead animals, it is utterly impossible on the vast range areas, often densely covered with brush, to accomplish this objective. Experiments carried out a number of years ago showed that the screwworm fly is capable of traveling considerable distances. For instance, marked flies have been recaptured 15.1 miles from the point of their release. Undoubtedly they go much farther than this. The operation of traps, therefore, serves a useful purpose in picking up the flies that breed in carrion overlooked in the clean-up work, and also those that migrate from adjacent territory.

Cooperative Trapping Increases Benefits

One of the greatest difficulties encountered in fly trapping is that of giving the traps proper attention. It is obviously poor business for ranchmen to purchase traps at \$2.50 to \$3 each and not to keep them in operation; yet this has often been done. The traps will not catch flies if they are not properly baited and emptied at regular intervals and repaired whenever necessary. This means that every trap must be rebaited every 10 days in hot weather and every 20 to 30 days in cooler weather, and the flies must be removed about every 30 days or oftener when they are abundant.

The usual experience has been that farmers and ranchmen neglect the traps during busy periods, and these are often the most critical times. This has suggested the idea of cooperative fly trapping. Such a scheme has been tried in the Menard, Tex., area and has proved workable. The county agent, in cooperation with the Bureau of Entomology, initiated the work and gave it general supervision. Such supervision is very desirable. With the pooled resources of the stockmen a reliable man is hired to care for the traps either at the rate of about 50 cents per trap per month or on a flat-wage basis. The larger the territory covered in the trapping operations, the greater are the benefits. It is believed that the extensive use of this method of screwworm control will be fully justified by the resulting reduction of losses caused by this pest.

F. C. BISHOPP, *Bureau of Entomology.*

FOALS Deprived of Dam's Colostrum May be Saved by Feeding Horse Serum

The difficulty in raising orphan foals is probably greater than that encountered with the young of any other species of farm animal. How much of this difficulty has been due to the failure of the foal to receive the first milk, called the colostrum, is not known, but horsemen have come to recognize the urgency of having the foal receive colostrum from its dam as soon as possible after the new-born animal is able to stand on its feet.

There is a belief, common among horsemen, that colostrum is important chiefly as a laxative to facilitate the early passage of the meconium

from the intestinal tract of the foal. It has been the custom, therefore, when for any reason colostrum is not available for the new-born foal, to administer a laxative to facilitate this elimination. Another role sometimes attributed to colostrum is its high concentration of nutritive elements in a form easily digested by the young animal.

Protective Function of Colostrum

The results of scientific research on the functions of colostrum have indicated also that, in at least some species, colostrum serves to immunize the new-born animal passively against bacteria for which its dam has already acquired immunity. Although in some species the immune substances present in the blood of the maternal animal are transmitted to the fetus through the placental circulation, as in man and the rodents, in other species, including the sheep, cow, goat, and horse, the placenta is of such structure that such transmission does not normally occur. In these last-named species, the blood of the young is lacking in the antibodies, or protective substances, which are present in the blood of the dam. There is, however, in the colostrum a concentration of antibodies several times as great as that in the blood of the same animal. There is further experimental evidence that in each of these types, the suckling young absorbs these substances from the colostrum it ingests during only the first 24 to 48 hours of its life. After this period no such absorption is found.

In 1922, Theobald Smith, formerly of the Department of Agriculture, and Ralph Little published the results of the first of a series of experiments which demonstrated conclusively the essential role of colostrum in the survival of new-born calves. They found that from 75 to 80 percent of calves which did not receive colostrum died of a generalized *Bacillus coli* infection, whereas control calves which received colostrum all survived. Since the organism *B. coli* is nonpathogenic for adult cattle, they concluded that "the function of colostrum is essentially protective against miscellaneous bacteria which are harmless later when the protective functions of the calf have begun to operate." Doctors Smith and Little further showed that calves can efficiently utilize cow serum either fed or injected, as an agent for such immunization, and were successful in using cow serum as a substitute for cow colostrum in rearing young calves.

Experiments with Horse Serum

In an effort to determine whether such findings would apply to equine stock, an experiment was conducted by the Department to determine the effect of substituting horse serum for horse colostrum in the raising of foals when their value justifies such a procedure. The technic for obtaining serum suitable for injection requires greater care than that for material to be fed. Moreover, the technic for injection requires more skill than for feeding. Consequently, in view of the practical nature of this experiment the serum was administered to the animals principally by feeding. A group of 13 new-born foals at the United States Animal Husbandry Farm, Beltsville, Md., was used. All were kept under the same conditions and surroundings and were handled similarly and fed similarly except in respect to the diet they received. The first lot, consisting of 3 foals, received neither colostrum nor serum, but only a milk preparation composed principally of dried

cow's milk, sugar, and water. Although the meconium was passed within 8 hours after delivery, and there were no evidences of constipation, each of these animals showed definite evidences of illness about 40 hours after birth. Two of them lived only 42 and 57 hours, respectively, both dying of septicemia produced by the *Shigella equirulis* organism. The third foal lived 12 days and died of a general septicemia attributed to a strain of *Salmonella paratyphi*, although the *Shigella equirulis* organism was also present in the tissues. Both of these organisms are commonly associated with the so-called "joint and navel ill" in foals.

Shigella equirulis is widespread among horses and in barns but is nonpathogenic to the adult horse. It would appear that the adult horse has built up a resistance toward this and other commonly prevalent organisms, which is transmitted under normal conditions to the foal through the colostrum. But a foal which fails to receive passive immunization through the colostrum or some other source appears unable to combat an infection, when once invaded by organisms.

Another lot of 3 foals was fed mare's colostrum during the first 12 hours after delivery, and mare's milk thereafter. These foals grew normally and had no symptoms of ill health.

Serum Fed Fresh and Dried

The remaining 7 foals received a suitable quantity of horse serum in addition to a milk preparation of the same composition as that fed to the first lot of foals. The serum was fed in two different forms, fresh and dried, both apparently being equally efficacious. The serum was obtained from healthy mature horses by drawing 2 or 3 liters (about 2 or 3 quarts) of blood at a time from the jugular vein. After the defibrinated blood had stood for from 6 to 8 hours, the clear serum was siphoned off the cells. This fresh serum was fed within 5 or 6 days after the blood was drawn.

About 4 liters (about 4 quarts) of serum obtained as described were dried in a partial vacuum at room temperature. This dried serum was fed within 3 months after its preparation. When desired for feeding it was dissolved in sufficient water to make it up to its original volume; that is, about 8.5 parts of dried powder were mixed with 91.5 parts of water. This fluid was then incorporated in the milk mixture and fed to foals. Since in this study the foals were receiving a mixture composed principally of dried milk, sugar, and water, the serum, whether it was fresh or dried and redissolved, was used to replace an equal volume of water in the milk mixture.

Six of the last lot of seven foals were each fed three fourths of a liter (about three fourths of a quart) of serum per 100 pounds of body weight between 6 and 18 hours after birth. Three of the animals received fresh serum, and three redissolved dried serum. In every instance the foal grew as a healthy, thrifty animal, with no symptoms of ill health. In the case of the seventh foal, however, the administration of serum was delayed until from 40 to 48 hours after birth. This foal was definitely ill before serum feeding was begun. No obvious effect was obtained from the feeding of 1 liter (about 1 quart) of fresh serum at this time. Injections of serum on the fourth and fifth days after birth were apparently responsible for a reduction in the swelling of the joints and an improvement in the diarrhea.

Mention has previously been made of the ability of several species of new-born animals, including foals, to absorb protective substances from colostrum fed within the first 48 hours after birth. Experimental evidence on the relation between degree of protection achieved and the age of young animals is limited. Yet, logically, the earlier a foal receives the protective substances in the colostrum or serum, the smaller the quantities required for efficient protection. The small number of animals used thus far in experimental work on this subject and the conditions of exposure do not warrant broad conclusions or recommendations involving the use of horse serum in raising colts. Besides, the limited facilities and the cost of obtaining adequate quantities of the serum will scarcely justify its present use for orphan foals of ordinary grade. However, in the case of valuable foals for which no colostrum is available, the information here presented suggests a promising means of protection against the ills of early life. The services and advice of a qualified veterinarian are advisable in obtaining and administering the serum.

I. P. EARLE and J. A. GAMBLE,
Bureau of Animal Industry.

FOREST Fires in Florida Are Fought with Water and Motorized Equipment

The national forests of Florida are highly inflammable because of the character of the ground cover and the common occurrence of relatively high temperatures, low humidity, and strong winds. These last three factors, and the sandy soil tend to diminish the effect of a heavy annual rainfall. Forest fires once started spread with great rapidity. They are usually driven forward by strong winds and make a "run" in a narrow strip a mile or more in length, often developing two or more "heads" or "leads."

The forests are situated in an area of virtually level terrain, and it is possible to drive an automobile or truck through the woods in most places. Longleaf pine is the predominating timber species, with slash pine found on the moist or "pond" sites, which afford the forest protection from repeated fires. In these generally open stands of pine the ground cover consists of grass, scrubby oaks, and an accumulation of oak leaves and pine needles of varying density, depending on the frequency with which a given area has been burned over.

Fires for the most part are confined to small areas because of the prompt discovery made possible by strategically located look-out towers from 80 to 100 feet high. In these towers look-out men, the eyes of the fire-protective organization, are constantly vigilant during periods of probable fire occurrence. They discover the first wisp of smoke and telephone the alarm. Fire fighters and equipment are immediately dispatched to the scene of the fire.

To meet the demand for rapid action in suppressing fires, the forests are gradually being gridironed with roads, motorways, and firebreaks. In spite of these improvements, however, a fire, given favorable conditions, will make a terrific run and jump the firebreaks. In this case the "head" must be stopped at all costs. Once the "head" is stopped, the flanks are relatively easy to extinguish.

During the last decade the use of water and motorized equipment has come to be recognized as an invaluable aid in fire suppression.

Forest officers of the Choctawhatchee, Ocala, and Osceola National Forests in Florida, have developed fire trucks equipped with 250- to 300-gallon water tanks, pumps, and hose (fig. 52). The pumps are so operated by the truck motor that water is pumped while the truck is either in motion or stationary. Each truck carries 50 feet of rubber garden hose with small nozzle. The pumps can be used to supply the hose or to fill the water tank from a nearby creek or pond by means of a suction hose. The

FIGURE 52.—One and a half ton truck equipped with 240-gallon water tank, plunger-type force pump operated from power take-off to truck transmission, six back-pack spray cans, drinking water, and 12-man tool outfit.

trucks are equipped with heavy bumpers and heavy-duty tires, and light armor protects those parts most liable to injury from saplings, stumps, and snags. Two or three men are assigned to each truck. A truck driver operates the pump while he drives the truck; a nozzle man walks or trots ahead of the truck and directs the stream

of water directly on the flames (at times this man literally wades in fire), and a nozzle-man's helper keeps the hose free from entanglements.

With this equipment it has proved possible to break the "head" of a fire by the application of water, which cools down the fire sufficiently to allow fire fighters to attack it directly, or build a fire line close to the flames. Water is not depended upon for 100-percent extinguishing, but is used only as an aid to manpower, as the amount of water available is limited to the capacity of the tank on the truck. Every gallon must be utilized to the maximum, and great responsibility rests on the nozzle man, who must be well trained and experienced.

Once the head of the fire is checked, the trucks turn to the flanks. Here, followed closely by fire fighters equipped with rakes and special tools, the truck crew cools off the hot line, so that the fire fighters can attack the fire directly. The easily accessible terrain permits the truck to follow the burning fire line through the forest. Small scrubby oak and small pine saplings are pushed over by the heavy bumper as the truck plows its way through the brush. There is much dodging and maneuvering of stumps and logs, but truck crews know their job.

FIGURE 53.—One half ton truck equipped with 50- to 60-gallon water drum, a hand force pump, 5-gallon back-pack pump, tool box, and miscellaneous tools.

Occasionally forest officers are required to combat a fire with a "head" so wide and traveling so rapidly that a direct attack is impossible. In such cases the fire fighters choose as a defensive line a road, motorway, or previously constructed firebreak from which to back-fire. In back-firing care must be exercised to prevent the back-fire from getting out of control. Here again the tank truck plays an important role by aiding in preventing the back-fire from spreading in the wrong direction. The back-fire must burn against the wind into the oncoming conflagration. Thus one fights fire with fire.

Under some conditions previously prepared defensive lines are not available and light tractors with disk plows or light graders are rushed to the scene on a large motor truck and trailer. This equipment is unloaded, and a fire line is plowed in advance of the spreading flames, and the back-fire is started. The tractor and plow are often capable of suppressing the flank of a fire by plowing one furrow very close to the burning edge of the fire.

In all phases of fire suppression in the Florida national forests motorized equipment is playing an important part (fig. 53). It is especially adaptable to Florida conditions and great possibilities exist for the extension and development of its use.

H. O. STABLER. *Forest Service.*

FORESTS Helped by Thinnings Made under "Free Use" Provision Free use of dead, down, and insect-infested timber and material from thinnings on the national forests is granted to settlers, miners, and other residents for firewood, fencing, and domestic purposes, by regulations of the Department of Agriculture. Large numbers of farmers located within the Black Hills and

FIGURE 54. — Men of the Civilian Conservation Corps thinning a stand of ponderosa pine.

Harney National Forests, S.Dak., and the surrounding territory, avail themselves of this privilege annually. On account of the drought and grasshopper plagues that have prevailed in western South Dakota, in recent years as well as the general agricultural depression, the number of people who have applied to the Forest Service for free-use material has more than doubled. A total of 5,200,000 board feet of free-use wood products was removed from these two forests during 1932 by 1,709 people. The removal of this kind of material is an improve-

ment and protection to the forest, and takes care of the needs of local farmers and miners, so that a two-fold purpose is served.

A practically treeless farming country surrounds the Black Hills section, and in addition to the need for firewood, there is also a demand on the national forests for fence posts, corral poles, shed rafters, etc. For some of these purposes, material from small, green trees can be used. In these forests are thousands of acres of overcrowded pole-size stands of ponderosa pine supporting from 2,500 to 3,000 trees or more to the acre. The trees are growing so close together, and the competition for light and moisture is so intense, that the growth of the entire stand is retarded. Further-

FIGURE 55.—Overcrowded stand of ponderosa pine pole-size trees which it would be advantageous to thin.

more, these dense stands of saplings and poles are a tremendous fire hazard to the national-forest property, since fires in such stands quickly jump into crown fires and are hard to combat.

During the summer of 1933, the labor of the young men in the Civilian Conservation Corps engaged in general forest-improvement work was directed toward making needed thinnings, and much was accomplished. By the end of August they had completed thinnings on a total of 5,640 acres (fig. 54). Arrangements were made between the forest supervisors and the State relief director for the shipment of 500 cars of firewood, taken from areas nearest to the railroad, for use in relief work during the succeeding winter. The State relief committee assumed responsibility for hauling the material to the railroad and the men of the Civilian Conservation Corps loaded it.

In addition to the work of the Civilian Conservation Corps, the wood products given to farmers under free-use permit has increased materially the acreage thinned. Strips for thinnings were laid out and labeled conspicuously with the permittees' names and addresses. This inspired each permittee to take a personal pride in doing good work on his strip. The demand from farmers for products under the system of free use is increasing steadily, since the work can be done during seasons of the year when farm work is slack.

A forest officer marks with a bark blaze or spot of paint the trees to be left, from 500 to 600 to the acre. These trees are the best in the stand and are selected for their form, thrift, proper spacing, and the possibilities they have for making fast growth after being released from competition (fig. 55).

The material cut in making thinnings is given to the permittees free of charge in exchange for cutting it. Both parties to the transaction benefit—the permittees obtain material useful for farm purposes, and the forest gets a much-needed thinning, which results in increased growth of the remaining trees, reduces the fire hazard, and beautifies the locality.

Dense stands of pole-size trees constitute a thinning problem everywhere, and it is probable that the system started on the Black Hills national forests, or a similar one, may be worked out for many agricultural communities adjacent to other national forests.

THEODORE KREUGER, *Forest Service*

FOREST Management in the Northwest Making Progress

Steady progress in sustained-yield management on the national forests of Oregon and Washington is shown in the completion of detailed management plans for important forest units and the starting of timber-cutting operations on sales made under these plans. The area contains 22,972,386 acres of national-forest land, of which 17,580,000 acres is potential commercial-forest land. Eleven approved plans now cover a total area of 2,250,575 acres, and two completed plans not formally approved cover 997,169 additional acres. Approved and completed plans together comprise 14.1 percent of the total. Planning progress during recent years has been at the average rate of about 277,200 acres a year.

Sales of timber have been made on 8 of the 11 working circles covered by approved management plans, in accordance with the stipulated policy, including regulated cutting.

In the heavy Douglas fir forests of western Oregon and Washington the ideal unit of management is a large watershed of from 75,000 to 100,000 acres of productive forest land containing from 3,000,000,000 to 4,000,000,000 board feet of timber. In this area the entire production of the working circle can go into the general lumber market, and the plan can be based upon the maintenance of a single logging operation. The plan provides for the regulation and limitation of the cut according to an assumed rotation or term of years within which the forest area within the circle will be cut over. This period may vary from 70 to 110 years depending upon the character of the stand, site quality, rate of growth of the timber, and the product which it is desired to grow. Pulp timber, for example, can be grown in a much shorter time than saw timber. The fundamental principle of each plan

is to so regulate the cutting that when operations have continued through the first cycle and covered the working circle, they can be maintained on the new crops of timber. The clear-cutting system is

FIGURE 56.—Young Douglas fir which has come in on logged-off land as the result of protection.

practiced in the Douglas fir type with provision made for natural reproduction from seed trees, left sometimes singly but more often in strips,

FIGURE 57.—Cut-over ponderosa pine with seed trees and reserve stand left after logging.

groups, or blocks (fig. 56). When this is impracticable artificial restocking may be resorted to.

In the ponderosa pine type, east of the Cascade Range, a somewhat different system is followed. Trees of all ages are commonly present

in the forest, and it is feasible to reserve the younger, thriftier trees as the nucleus for a new crop to be cut in about 60 years. The first cutting removes about 80 percent by volume of the total stand or a little more than half of the trees. Protection of advance reproduction during logging is an important feature, since this young growth must be depended upon to a large extent for the third crop on which cutting will begin about 120 years after the first cutting (fig. 57).

Owing to the lighter stands per acre and slow growth of the timber, the maintenance of even a fair-sized logging operation requires a very large working circle. One such circle within which the permissible cut during the first 60-year cycle has been placed at 60,000,000 feet annually, includes a productive area of 429,239 acres.

The aim of forest management in all types is to keep forest land productive and to so regulate the rate of cutting that the communities dependent on established lumber-manufacturing plants may be assured of a continuous crop of raw material.

FRED AMES, *Forest Service.*

FUR-BEARING Animals May Be Increased by Wise Management and Protection

The animals of the United States which since long before the advent of the white man have provided the finest furs have been forest dwellers. The marten, the fisher, the otter, the mink, the fox, and the beaver—all now relatively few in numbers—and some animals locally extinct over wide areas formerly inhabited the forests in countless thousands.

Their near-extinction cannot be accounted for entirely by extension of human settlement. Thousands of acres of forested land, especially west of the Great Plains, are sparsely settled. Uncontrolled trapping for market, the "killing of the goose that laid the golden egg" is largely responsible for their disappearance. There is yet time, however, to save the remnant of most of the species and to increase them to productive numbers in years to come. In the western part of the United States most of the rough and relatively inaccessible mountainous areas are in the national forests. Such areas are the natural home of most of our best fur-bearers. This country is not adapted to agricultural settlement, and no doubt will be kept in forests for all time. Therefore, if an adequate basic breeding stock can be brought back by protection and thereafter only a reasonable natural increase taken annually, the present scarcity of fur-bearing animals can be overcome.

Take, for instance, the situation in Colorado. There are 14,751,660 acres of rough mountainous territory in the 14 national forests located within the boundaries of the State. Estimates made annually for years, by forest rangers who are out in the forest the year around, indicated in 1931 the following numbers of various fur-bearers: Weasel, 42,000; beaver, 40,000; muskrat, 22,000; marten, 7,500; mink, 7,000; skunk, 4,700; badger, 4,100; and fox, 3,400.

Where are the fisher and the otter, both denizens of old of the dense forests of this State? Where are the thousands of martens, minks, and foxes that formerly inhabited this territory? Where are the hundreds of thousands of weasels whose winter fur is that of the ermine? Gone or greatly reduced in numbers, because of no adequate regulation of trapping for market or control of the summer vacationist with the

small-caliber rifle or pistol who shoots at any unusual or strange animal. Many animals whose fur would be valuable in winter are thus killed in summer, when their pelts are worthless on the fur market.

Laws Inadequate to Protect Fur-Bearers

The control of hunting and trapping of fur-bearers even in the national forests is under the authority of the State. Most States of the West have inadequate laws for the protection of fur-bearers. Colorado has practically none. The only fur animal receiving protection under the State law in Colorado is the beaver. This easily trapped animal and valuable irrigation-water conservator has responded to protection. This indicates that greater numbers of other animals not so easily trapped might be expected if given reasonable protection. Practically all the beavers in Colorado are in the national forests, where there is natural territory for at least twice the present number.

The essentials of a law protecting a basic supply of fur-bearers and providing for the utilization of the surplus annually, are: (1) Total protection except when the fur is prime. This will automatically protect animals during the time of breeding and raising young. (2) Limitation of kill, annually by individuals and according to territory. (3) Allocation of territory to individual trappers.

Fur farming may well supplement, though it does not promise to supplant the natural production of fur. Success in fur farming has thus far been limited to a few species. For some of these the profits have resulted to some extent from the demand for breeding animals. As in other lines of breeding, such stock commands higher prices than would the skins. The Bureau of Biological Survey has studied the many phases of fur farming, but up to the present its efforts with native wild animals have been primarily concerned with foxes and minks, the species best adapted to production in captivity. Through control of mating, however, the fur farmer has produced several popular color phases, and by proper selection he can undoubtedly produce animals of superior fur quality. These farm-raised animals will naturally be few as compared with the potential abundance in native habitat. Fur farming will not soon solve the problem of pelt production as regards the marten, the fisher, and the otter, the raising of which has thus far proved more difficult than that of foxes and minks. Wise management to maintain adequate breeding stock for reproduction in its natural state will continue to be necessary.

L. H. DOUGLAS, *Forest Service.*

GAME and Other Wild Species Suffer Heavy Losses from Disease

Continuous observations over a period of several years have afforded many opportunities for recognizing that some of the more serious and extensive losses of wild life, though attributable to natural causes, are probably preventable. The old ideas that wild subjects in their native environment are always healthy, and that when death overtakes them it is due either to old age, to attacks by predatory species, or pursuit by hunters and trappers, have been proved erroneous. The fact that fur-bearing animals and game birds frequently develop to a larger size when propagated under the control of man, free from disease and parasites, gives

evidence that when forced to seek their own livelihood and protection they must endure many rigors, some of which are fatal and others which merely stunt their growth. This dwarfing is especially noticeable, however, in overpopulated environments, and is found to be due to insufficient food, disease, and parasitism.

Of greater importance are the extensive losses occasioned by epizootics over wide areas and affecting great numbers of individuals. Perhaps the best-known example of this is the "western duck sickness", properly termed botulism, which is so highly destructive to waterfowl and shore birds frequenting certain alkaline lakes in the West. These losses are greatest late in summer and in the fall, when the combined factors of abundance of decaying organic matter and shallow alkaline water warmed by long exposure to the sun, form the necessary conditions for rapid growth of the causative organism, *Clostridium botulinum*, type C. A potent toxin is produced by this bacterium, and when birds in these areas ingest this with their food, death ensues quickly. More than 8,000 birds have been counted per mile of shore line, where they had died or had been carried by wave action. Gulls appear to be relatively resistant to this toxin, but most species of waterfowl and shore birds are found to be susceptible and to succumb if they take a sufficient quantity of the poison.

Pollution of the waters by industrial waste and oil likewise accounts for many waterfowl losses. The oil acts only as a physical handicap to the birds, whose feathers become saturated, and their death results from cold, starvation, or drowning. Other substances that pollute the waters, such as lead picked up as shot pellets, and phosphorus, dropped in the waters over which explosives are sometimes fired, kill because of their actual toxicity. Unlike botulism, the extensive losses from which are confined chiefly to the western alkaline lakes, the losses caused by water pollution are observable throughout the United States in all types of fresh water.

Cyclic Disappearance of Species

It has frequently been noted that great numbers of the more important species of upland game birds and fur-bearing animals disappear at more or less regular intervals. During the past few years the seriousness of these periodic disappearances has caused increasing concern among conservation officials and other wild-life administrators. Since it is not feasible to propagate many of the wild forms under controlled conditions, increased efforts are being made to combat the waste occurring in these cycles in some of which the populations are almost wiped out.

Typical areas that have suitable cover and support a variety of wild species have been surveyed by cooperators of the Bureau of Biological Survey, and plans are being developed for making a careful study of the resident and other fauna over a succession of years. Observers will note the cause or causes of the losses over at least one complete cycle, from the period of abundance through that of scarcity. The most spectacular declines in wild-life population as a rule follow periods of greatest abundance, and it is demonstrable that in dense populations of susceptible subjects, virulent diseases have the opportunity to cause the greatest destruction and waste, but that they are for this reason self-limiting.

In areas now being examined by the Biological Survey and its co-operators, tularemia has been encountered not only in rabbits, but also in a wide range of other species and in many widely separated localities. Insects that transmit this and other diseases are abundant. During the year 1933 the Bureau and its co-operators demonstrated that ruffed grouse and sharp-tailed grouse are susceptible to tularemia. It is not assumed, however, that this disease alone is responsible for the present serious losses among game.

Investigations on diseases of wild life are being conducted in greatest detail in Minnesota through the cooperation of the State university with the Bureau of Biological Survey. Special efforts also are being made to correlate the observations with conditions existing in other parts of the United States and in Canada. It is expected that the information to be derived from the studies will enable wild-life administrators to institute measures to curtail the extensive but probably preventable waste in wild-life resources from natural causes.

J. E. SHILLINGER, *Bureau of Biological Survey.*

GAME Preserve on the Wichita National Forest, a Museum of Natural History

In 1901, when the Apache, Comanche, and Kiowa Reservations in the old Indian Territory in southwestern Oklahoma were opened to settlement, 61,480 acres of semimountainous lands were retained as the Wichita Forest Reserve.

The administration of the area was transferred to the Department of Agriculture in 1905, and in the same year it was further designated a Federal game preserve.

Since March 1907 it has been known as the Wichita National Forest and Game Preserve. Herds of big game have been developed here under the United States Forest Service game management method (fig. 58).

In 1906 hunting and trapping regulations were issued by the Secretary of Agriculture, and Congress

FIGURE 58.—White-tailed doe and triplet fawns.

appropriated \$15,000 to enclose 8,000 acres with buffalo-proof fence. Plans are approved for fencing the entire boundary with a game-proof fence. Fourteen miles of fence were constructed in 1931, and the work is being continued in 1933 under the Emergency Conservation Act. Good roads to the preserve have been constructed and camping places provided.

The area consists mostly of oak-clad, boulder-strewn hills, interspersed with valleys, parks, and streams skirted with pleasant groves. The average elevation is about 1,700 feet above sea level.

Post, black jack, and red oaks make up 90 percent of the woody cover; elm, ash, native walnut, pecan, mulberry, persimmon, hackberry, and cedar about 10 percent. The native species furnish important cover and food for wild life and add much to the natural game values. Plantations of cedar, Osage-orange, black walnut, and black and honey locusts have been established, and further planting is

FIGURE 59. —Some members of the breeding herd of buffaloes on the Wichita National Forest and Game Preserve.

planned. True buffalo grass (*Bulbils dactyloides*) and its near relative, grama grass (*Bouteloua* sp.) are important constituents of the herbaceous vegetation.

White-tailed deer was the only big-game species remaining on the land at the time the forest was established. This species now numbers about 400.

FIGURE 60.—Wild turkeys.

Fifteen buffaloes (9 cows and 6 bulls) representing four distinct strains of blood, were received from the New York Zoological Gardens through the special interest of W. T. Hornaday and the American Bison Society, in October 1907. After some early losses from tick fever, the herd prospered and now numbers some 282 animals (fig. 59). A considerable number has been sent out as planting or exhibition

stock for parks and zoos. A bull known as "General Lawton", the last of the original herd, succumbed in 1930 at the mature age of 25 years. One cow attained the age of 29 years. Another of the original herd gave birth to a calf at 24 years. Inferior animals have been eliminated with a resultant high type of herd.

Twenty-one elk were imported between 1908 and 1912, 20 of which were from the vicinity of Yellowstone Park. The present estimate of these animals is about 365 head. A number have been shipped to zoological gardens.

Two shipments of antelope were tried, but the species has not thrived, and the sole survivor died in 1931. Further importations are contemplated.

In 1912-13, 24 wild turkeys from Missouri and Oklahoma points were planted. It is estimated that the forest now harbors at least 700 of these birds (fig. 60).

Of special interest was the introduction in August 1927 of 26 old-type longhorn cattle under a special act and appropriation of Congress. The

purpose is to save from extinction this unique type of cattle so important in the early history and development of the range country. This herd has thrived and now numbers some 96 head (fig. 61).

In the management of the Wichita National Forest and Game Preserve the plan is to restore, control, and protect species formerly in-

FIGURE 61.—An old-type longhorn steer.

digenous to that locality and keep them in their natural environment as much as practicable; to provide a reservoir of planting stock for States, parks, and other agencies interested in wild life; to conduct, with the cooperation of the Bureau of Biological Survey, natural-history and biological studies which will be generally useful in game studies and management; and to provide a large outdoor museum in natural history for the thousands of people from many sections of the country who yearly visit and enjoy the wild life, the natural beauties, and the historic interest of the area.

JOHN H. HATTON, *Forest Service.*

GRASSHOPPER Control More Effective When Undertaken at Beginning of Outbreak

Grasshopper infestations of greater or less extent and severity occur somewhere in the United States nearly every year.

Almost invariably such infestations follow the occurrence of 2 or 3 dry seasons. Occasionally when such conditions exist over an extensive area and for some reason artificial control is not obtained, a very serious and widespread outbreak results.

Extent of the Present Outbreak

Such was the beginning of one of the most destructive grasshopper outbreaks of record in this country. In 1930 two species, the differential and the two-striped grasshoppers, were observed to be building up in unusual numbers in the Dakotas, Minnesota, Nebraska, and Iowa. In 1931 this outbreak reached a destructive status, resulting in heavy crop losses over hundreds of square miles of farm country in south-central South Dakota, northeastern Nebraska, northwestern Minnesota, northeastern North Dakota, and northwestern Iowa, and less severe damage in adjoining areas (fig. 62). In 1932 a cool, wet spring,

FIGURE 62.—A field of corn in South Dakota destroyed by grasshoppers in 1931. The trees around the buildings at the upper right of the picture were also completely defoliated.

with unusually heavy, driving rains, was followed by a general reduction in the numbers of grasshoppers in Nebraska, Iowa, and South Dakota. The excessive moisture from these rains also produced a very rank growth of native vegetation as well as of cultivated crops, so that such hoppers as survived the unfavorable climatic conditions were furnished ample food for development without any considerable feeding in cultivated areas. Small grains and hay crops remained practically unharmed, and the only damage observed was to corn as a result of the drying up of native vegetation late in the season. In North Dakota and Minnesota, however, conditions were quite different because of the unusually dry spring as contrasted with the abundant rainfall farther south; consequently, for the year 1932 the center of the most destructive infestation shifted to northwestern Minnesota and northeastern North Dakota. At the same time a third species, the clear-winged or warrior grasshopper, increased to outbreak numbers, and a fourth, the lesser migratory grasshopper, began to appear in injurious numbers.

Infestation in 1933

The season of 1933 was characterized by a general and severe infestation over practically the whole of North Dakota, extending southward into central and eastern South Dakota, northeastern Nebraska, and westward over eastern and northeastern Montana, with less severe infestations in Idaho, Wyoming, Minnesota, Wisconsin, and Michigan, and in sections of practically all the other Western States. The lesser migratory grasshopper, either a direct descendant or a close relative of the Rocky Mountain grasshopper of old, which caused so much damage during the early settlement of the Plains country, became abundant over a much larger area and was the most threatening species in North Dakota, northern and eastern Montana, and the northern portion of South Dakota. This is by far the most dangerous species from the standpoint of general migrations. During the building up of this infestation in the northern Great Plains there was a corresponding development in the neighboring Provinces of Canada.

Control Handicapped by Economic Conditions

During the winter of 1930 and the early spring of 1931 attention was called, both through the press and by radio, to the building up of the infestation just described, and appropriate recommendations for control were made. The financial condition of the farmers, as well as of the States and infested counties in the northern Great Plains, prevented them from obtaining funds adequate to finance an effective control campaign. This condition persisted, and early in 1932 the President requested an appropriation of \$1,450,000 to aid, by Federal supervision and purchasing of materials, in a general control campaign in this area. This and other efforts to obtain Federal funds for such a campaign failed. The Minnesota State officials, however, carried through the general plan as it applied to that State and, by the use of a State appropriation of \$250,000, conducted a successful control campaign. In North Dakota many counties used available funds for control, and considerable good was thus accomplished, although full value was not possible because of lack of complete coordination and unified control effort.

Because of the failure to obtain a Federal appropriation for the control of this outbreak in 1932, no concerted attempt was made to obtain Federal funds directly to finance control work in 1933. However, as the season developed, and hordes of young hoppers began to migrate from their hatching grounds, frantic appeals were made for Federal help. Such attempts to obtain funds from the Reconstruction Finance Corporation, the Federal Emergency Relief Administration, and the Farm Credit Administration, as well as from regular departmental appropriations, revealed the fact that either no funds were available or authority to use available funds for grasshopper control was lacking. The result was a continuation of the campaign by State authorities in Minnesota, effecting a further reduction of the infestation in that State, with little or no loss of crops. In North Dakota 15 or 20 counties attempted control on county bases, and considerable good was done, although owing to the lack of concerted effort on a State-wide basis, with no effort whatever in some counties, there was little improvement in the situation in this State as a whole. In South Dakota no control work was done, while in Nebraska, Colorado, Montana, and

Idaho fairly effective work was done on a county basis, in some cases, as in Nebraska, with the assistance of State funds.

Serious Damage Expected in 1934

From information available in the fall of 1933, destructive grasshopper infestations are to be expected in 1934 in North Dakota and South Dakota, northeastern Nebraska, northern Wisconsin, northern Michigan, northern Wyoming, throughout most of Montana, and in many sections of practically all the Western States. It is both interesting and important to note that in Minnesota, where a State-wide campaign has been effectively carried out for 2 years, the grasshopper population is almost normal, in contrast to the heavy infestation now existing in the surrounding States, where no concerted efforts have been made toward control.

Unless weather conditions unfavorable to grasshoppers should prevail over the extensive area just mentioned, the outlook for destruction by grasshoppers in 1934 is more serious than for any previous year of the present outbreak.

W. H. LARRIMER, *Bureau of Entomology.*

GRAZING Loss by Poisonous Plants Reduced on Ranges by Eradication of Plants

Obnoxious range plants in the national forests include species poisonous to livestock, plants that cause mechanical injuries, and aggressive plants of little economic value that crowd out valuable vegetation. The seriousness of the poisonous-plant problem is indicated by the fact that on the national forests the annual loss to stockmen from poisonous plants is approximately half a million dollars. In some instances obnoxious species have become established following the destruction of more valuable plants by fires, overgrazing, etc. In such cases the original plant association may often be reestablished through management which will afford adequate protection to the preferred species. In the case of particularly aggressive plants or poisonous plants which cause serious losses of livestock often the only effective solution is to destroy the plants.

The more common means employed to eradicate undesirable plants include grubbing, mowing, and the use of chemicals. Although various chemicals are being used successfully for killing plants on a small scale, their cost is so high and the technic of applying them so imperfect that the Forest Service has not felt justified in undertaking this method of control extensively. The principal method employed to date has been grubbing. The principal group of plants operated on are the larkspurs. These plants are responsible for a larger percentage of losses among cattle than any other class of plants on the national forests. Where they occur concentrated in patches on range of high carrying capacity, their eradication is often justifiable, in view of the fact that a larger acreage of good range is made safely usable by this means, even though such control is relatively expensive if charged only against the acreage treated. According to results of investigations carried on by the Bureau of Animal Industry, when leaves from normal plants that have not yet formed flower buds are eaten, a quantity as little as 0.5 percent of the animal's weight, if eaten within the space of an hour or so, is likely to poison the animal, and 0.7 percent may kill it.

At this stage of growth the stems have been found to be approximately one half as poisonous as the leaves. As plants grow older they are less injurious, unless larger quantities are consumed. If a longer space of time is required to consume a given quantity of the larkspur the likelihood of injury is less. If, therefore, the supply of living plants is reduced to a scattered stand the danger of livestock losses may be largely removed.

Extermination of Larkspur

The Forest Service, in cooperation with grazing permittees, has been active for several years in exterminating larkspur from areas where

FIGURE 63.—Tall larkspur as it frequently occurs in dense stands on western mountain ranges.

most serious losses have occurred (fig. 63). Altogether the plant has been cleared from more than 28,000 acres at an average cost of less than \$4 per acre, including regrubbing, which usually amounts to about 25 percent of the original cost. Under average conditions a man can grub about 200 plants per hour. Usually the reduction in losses of cattle in 1 or 2 years has offset the cost of eradication. Where it is not practicable to grub larkspur, on account of the rocky character of the land, the presence of dense stands of shrubs, etc., losses of cattle may be avoided by fencing the infested areas and excluding stock during the period when the danger is serious or until late in the season. In many cases such enclosures are used to advantage as pastures for saddle stock or as holding pastures for cattle during fall round-ups. Another effective way of avoiding losses from larkspur is to utilize

larkspur-infested range for sheep, since neither sheep nor horses, under ordinary conditions, are poisoned by larkspur.

Mowing has been found to be a useful means of ridding the range of some undesirable herbaceous plants where they occur in dense stand and where the surface of the land is such that mowing machines can be used effectively. By this means the current year's growth is removed quickly, but it is usually necessary to remove for at least 2 years in order to exterminate the plants. The most effective time to mow is during the early blossoming period.

There is a general interest on the part of experiment stations and commercial firms in the development of chemical plant killers. Effective results have been obtained by the use of such chemicals as sodium and calcium chlorates, common salt, arsenicals, sulphuric acid, carbon disulphide, ammonium thiocyanate, etc. General use of some of these materials under range conditions may be justified if the costs can be reduced sufficiently and, in the case of some, if the danger from poisoning or from combustion can be eliminated.

It is estimated that 1,338,360 acres on the national forests are infested with poisonous plants. Yearly reports indicate that the loss of livestock averages almost 6,000 cattle, valued at \$274,000, and 27,000 sheep, valued at \$175,000. Eradication of the plants or control of the area, therefore, becomes an important problem in range management. In the development of the plans for the Emergency Conservation Work program, attention was early directed to this project, and many emergency conservation camps in the vicinity of which poisonous plants exist have crews working on the eradication of such plants or control of the area infested.

R. R. HILL, *Forest Service.*

GREEN Mountain National Forest to Aid Development of Forestry in Vermont With the creation of the Green Mountain National Forest, on April 25, 1932, Vermont became a national-forest State. The total

area within the forest boundary is 102,100 acres, of which the Government has purchased 44,520 acres under the Weeks law. It is proposed to purchase the remaining forest lands within the boundary when they can be obtained at reasonable prices. The forest is being acquired under the sanction of the State and with the heartiest cooperation and support of the State forest officials.

The Green Mountain National Forest lies in the southwestern part of Vermont, and along the top and both slopes of the picturesque Green Mountains, east and west of Manchester in Rutland, Windsor, Windham, and Bennington Counties. It is accessible from U.S. Highway No. 7, which skirts it on the west, State Route No. 163, which lies just east and north of it, and Highway No. 11, which is on the south.

The entire forest was cut over in the past, much of it some 20 to 40 years ago. It now contains some merchantable timber, but most of its present stands are too young to cut, though they are fast approaching merchantability and maturity. In general, the forest is made up of thrifty young hardwoods with a small mixture of red spruce, fir, and hemlock. Near the top of the Green Mountains are some dense pure stands of spruce. The most important hardwoods represented are birch, beech, maple, and ash, and to a lesser extent various oaks and cherry. In general, the productive capacity of this forest is high; growth is relatively fast; and there is a young stand composed for the most part of valuable tree species.

The main purposes to be served by this forest are economic: (1) The protection of the headwaters of navigable streams to preserve the waterpower resources and the beneficial influence which the forest cover has on stream flow; and (2) the production of timber, both as a source of raw material for a permanent local wood-using industry and as a demonstration of proper management of Vermont woodlands under good forestry practices.

On the Green Mountain, as on other national forests, all resources will be developed under a coordinated plan of management which will fully realize the main objectives of watershed protection and timber production, and promote the possibilities for recreation and the enjoyment of wild life which the forest affords. To this end the forest has been organized under the supervision of the forest supervisor of the White Mountain National Forest, who has headquarters at Laconia, N.H., with immediate administration under a ranger stationed at Bennington, Vt.

Fire Danger Not Extreme in Vermont

Fortunately the forests of Vermont are not subject to extreme fire danger, although much damage has been done by fires in the past. The steep and rocky western face of the Green Mountains has been seared by fires which in places have killed the timber. To avoid such devastation on the new national forest, a fire organization has been set up and is functioning. In addition, a road system is nearing completion, which gives ready access to the forest, and by means of which the forest may be protected from fire, its products marketed, and recreationists brought to it.

Plans for the management of the timber on a sustained-yield basis are also taking form, and timber management is already being put into effect through sales of saw logs for consumption by local industries. Under these plans the annual cut of timber will be no more than the growth, and cutting will be so regulated that the watershed values of the forest will not be impaired. In the immediate future the amount of timber cut will necessarily be small because most of the timber stands are immature, but as the forest comes into full production, there will be a rapid increase in its annual yield of timber products.

During the year two civilian conservation camps of 200 men each have been established on the forest. These men are completing the secondary road and trail system, as well as putting the young timber stands into better growing condition, through release cuttings and thinnings. Their work will bear fruit through the production of better and heavier stands of timber in a shorter time than if the stands were left untouched by cultural operations.

Under Federal management the forest will give adequate protection to the watersheds, and it will not only produce raw material for a permanent local wood-using industry, but will also provide a demonstration that will be of value to the private timberland owner who may put into use the successful, advanced methods of forest management developed on the Green Mountain Forest. The forest will become, therefore, not only an aid to economic stabilization and an inspiration to the recreationist, but also a positive factor in the successful development of forestry in Vermont.

JOSEPH C. KIRCHER, *Forest Service.*

G YPSY-MOTH Control an Important Measure for Forest Conservation

Restriction of the spread of the gypsy moth and curtailment of the damage it causes to tree growth is of benefit to every citizen of the United States.

It is the successful application of the doctrine that "an ounce of prevention is worth a pound of cure."

An attempt was made by the State of Massachusetts to exterminate this insect during the period 1890-1900, but it failed because the public was misled into the belief that the work was unnecessary, as temporarily there was no perceptible widespread damage in urban districts. Drawing this incorrect conclusion proved to be expensive and has since cost the State of Massachusetts and its citizens nearly \$1,000,000 annually. Heavy expenditures on the part of the rest of the New England States, New York, New Jersey, and Pennsylvania, as well as on the part of the Federal Government, have also been necessary. The serious nature of the injury caused by this pest is fully recognized, as is shown by the continuous work that has been done by the States named and the Federal Bureau of Plant Quarantine to check the increase of the insect and to prevent its spread.

The States concern themselves principally with suppressing the pest within their borders, but the funds available are limited and are used largely for the protection of shade trees along roadsides, in public parks, and on private grounds, the work done in the forest areas being confined to a small amount in the more valuable stands. The work being done by the Federal Government has for its prime object the prevention of the spread of the insect on materials that are moved from infested areas to other parts of the United States, the restriction of local spread along the outside border of the infested area in New England, and the extermination of the insect in outlying colonies or isolated areas. Under the first of these purposes, the Department has been largely successful in preventing long-distance spread for more than 20 years. Local spread along the outside border of infestation has also been stopped for the last 10 years, and considerable progress has been made in reducing the infestation in many localities in the outside border territory, known as the barrier zone, in western New England and in New York State east of the Hudson River. In New England there is constant danger of infestations reaching the barrier zone from the territory directly to the east which is rather generally infested. Observations made during the past summer indicate that the insect is increasing rapidly in the territory adjoining the Connecticut River, particularly in New Hampshire, Vermont, and Massachusetts.

Progress in Isolated Colonies

Substantial progress has been made in exterminating the insect in hundreds of small isolated colonies, some of them in States west of New England, and a large infested area in New Jersey aggregating more than 400 square miles has been cleaned up, as well as a number of small colonies on Long Island. During the past year a vigorous gypsy-moth colony was discovered near Pittston, in the northeastern part of Pennsylvania. The insect must have existed there for at least 10 or 12 years, and the source from which it came has not been determined. The limits of the area involved have not been completely determined, but 230 square miles are now known to contain infestation. Vigorous measures are being taken to clear up this infestation which is difficult to handle on account of the mountainous nature of the territory. The work in these instances has been done in cooperation with the States concerned.

Experience has amply demonstrated that large areas can be cleared of this insect and that progress can be made in restricting the spread of the pest.

It is evident that the conservation of forest resources and the development of valuable forest areas to replace much of the waste land which is now unproductive and forms a breeding ground for dangerous pests, can be brought about only by taking such measures as will materially reduce the injury being caused. Certainly the successful prevention of the spread of the gypsy moth is a most practical form of forest conservation when the relatively small area now infested is compared with the enormous areas of susceptible forests in the United States that are in danger from this insect. The protection of these areas from infestation and the resulting damage certain to follow if the gypsy moth is allowed to increase are sufficient reasons for a vigorous policy for suppressing this insect. In addition to this, there is urgent need to preserve shade and ornamental trees and plantings. When it is remembered that the expenditures for gypsy-moth control by the New England States average over \$1,000,000 annually, and that most of the funds are spent on shade-tree protection, the importance of the problem is readily apparent.

Forest Conservation Vitally Necessary

There is no immediate prospect of overproduction of good forests; in fact their conservation, development, and protection has never been more vital to the Nation. Adequate protection from destructive pests eliminates waste and unnecessary drain on our national resources.

One of the difficulties constituting a real threat to effective forest development is the existence of enormous acreages of cut-over land in the infested area that are not only unproductive under present conditions but, because of poor varieties of tree growth, are in a state of practical abandonment. Few owners are financially able or willing to go to the expense of improving such stands. The gypsy moth thrives under such conditions and is able to increase and form reservoirs from which the species is dispersed. The prevention of the spread is made more difficult and control operations are more costly in nearby sections while these breeding places are permitted to remain.

HORSES and Mules Meet Need for Cheap Flexible Farm Power, Studies Show

largely responsible for relegating equipment to the background in farm operations. The fascination that mechanical power and its equipment had for the farm youth and the speed with which work could be done with such power also contributed to the decline in the numbers of horses and mules on American farms during the last decade.

Most farmers, however, have retained their work stock and equipment in the belief that the use of horses and mules was fundamentally cheaper, and more suitable for the wide range of field work, and that animal power would eventually adjust itself to modern requirements. In many States work-stock owners have made adjustments in this direction during recent years. Hitches have been devised eliminating side draft for working units of 4, 5, 6, 7, 8, or more animals in a single

Times of prosperity with attendant high prices for products of the soil and notable advances made in the efficiency of tractors were

much old-fashioned, horse-drawn equipment to the background in farm operations. team driven with one pair of lines. Such hitches enable the farmer to do his work rapidly, meeting a vital requirement. Moreover, the ability to use teams in varying-sized units gives a great flexibility of power, capable of meeting emergencies (fig. 64).

In the Corn Belt area of the Middle West, particularly, a pronounced tendency has developed toward the use of improved farm machinery pulled by animal-power units of various kinds and sizes. In many sections, even on farms of moderate size, the old walking plow has generally given way to the sulky and multiple-bottom gang plow, and the familiar 1-row walking cultivator has either been supplanted

FIGURE 64.—Six-horse tandem disk harrow and two-horse team on corn planter, illustrating adaptability of horse and mule units to varying field requirements.

entirely or supplemented by 2-row or other implements. Single-disk harrows, in turn, have frequently been either converted into tandem-disk outfits or replaced by them. The mechanical corn picker has become popular, and it is a rather common practice to perform two different tillage operations at one time.

Scope of Farm-Power Survey

That animal power is well-adapted to meet the demands of this new order of things is indicated by the extensive use of multiple or "big-team" hitches in the Corn Belt, and by the multiplicity of field operations for which animal power is now generally used. Information on these subjects has been obtained in cooperative farm-power studies which this Department conducted in various portions of the Corn Belt and Mississippi Delta, in 1929 and 1930. In Illinois, Indiana, Iowa, Michigan, and Missouri, work records obtained on 736 farms using 4,425 head of work stock showed that animal power was used quite generally for all kinds of farm field work and for farm and road hauling. In plowing, the number of work animals varied from a small unit of 2 head pulling a single-bottom 14-inch plow to 12 head on a 4-bottom 14-inch gang plow. The 12-horse team plowed 11.1 acres each 10-hour day at a cost of 69 cents an acre for animal power. An outstand-

ing accomplishment, both in rate of work and unit cost, was shown by 3-bottom plow outfits pulled by 7 horses. They broke 10.9 acres a day, at a power cost of only 41 cents an acre. Disking with 2 horses cost 27 cents an acre but with 12 horses the cost was reduced to 16 cents. The multiple hitches were made up of good, young horses and mules driven by able horsemen who were getting the most out of their power. Examples of representative field work in the Corn Belt, together with costs for animal drawbar power, exclusive of operator labor, are shown in table 3. Cost figures are for the period of July 1, 1931, to June 30, 1932.

TABLE 3.—*Field work accomplished by teams of various sizes, together with costs for animal power, on representative Corn Belt farms*

Operation	Horses or mules	Implement	Area per 10-hour day	Cost per 10-hour day	Approximate cost per acre
	<i>Number</i>		<i>Acres</i>		
Plowing (fall)-----	4	2-bottom 14-inch plow-----	4.1	\$3. 04	\$0. 74
Do-----	12	4-bottom 14-inch plow-----	11. 1	7. 68	.69
Plowing (spring)----	7	3-bottom 14-inch plow-----	10. 9	4. 48	.41
Disking-----	2	6-foot single disk-----	5. 7	1. 52	.27
Do-----	12	20- to 24-foot single disk-----	47. 8	7. 68	.16
Harrowing-----	6	32- to 33-foot spike-tooth harrow-----	75. 6	3. 84	.05
Drilling grain-----	4	10-foot drill-----	18. 1	3. 04	.17
Cultivating-----	3	2-row cultivator-----	13. 5	2. 28	.17
Mowing-----	2	5-foot mower-----	9. 8	1. 52	.16

Feed Required

The average time, per head, that these Corn Belt horses and mules worked on the farm in a year was 681 hours. The feed consumed per head was 3,205 pounds of concentrates, 5,166 pounds of roughage, and pasture for a period of 6 months. Generally, this feed may be regarded as fuel for which no cash expenditure was required.

In the Cotton Belt States of Mississippi and Arkansas, farm-power records taken on 161 plantations using 7,011 mules and horses indicate that work stock remains the primary source of motive power. There 87 percent of all drawbar work in the raising and harvesting of crops was done by animal power. Unlike the Corn Belt section, however, the South generally does not seem to have adopted large-sized hitches and the most improved farm machinery. The use of work stock in the South, as exemplified by records in the Mississippi Delta, again emphasizes the economy, versatility, and general utility of the four-legged power plant. Owing chiefly, perhaps, to the "cropper" system of production and to the fact that there generally is no shortage of man power, the hitches used most commonly consist of from 1 to 4 animals. The work done by such animal power usually consists of plowing, stalk-cutting, disking and other harrowing, rolling, bedding, fertilizing, planting, cultivating, mowing, raking, and hauling. The operations of bedding and cultivating required more than one half of the total number of hours spent on all work.

As a rule, the individual horse and mule in the South works a greater number of days in a year than do those in the West and Middle West. The survey records show an annual average of from one hundred to one hundred and twelve 10-hour days of plantation work for each animal used on the 161 plantations. Seventy-four percent of the animal labor was required for crop work. Fuel hauling, the next-largest power requirement, took about 11 percent of the total time.

The feed consumed, per head of work stock, on the 161 Delta plantations averaged 2,927 pounds of concentrates, 5,840 pounds of roughage, and pasture for an average period of 34½ days.

As compared with similar data already given for the Corn Belt, feed consumption in the South is observed to be, in general, somewhat less. This is due in part to smaller size of work animals, which on the plantations studied weighed on an average several hundred pounds less than those used on the Corn Belt farms.

Data on representative field work for Delta plantations, together with costs for animal drawbar power for 1929, are given in table 4

TABLE 4.—*Field work accomplished by teams of various sizes, together with costs for animal power, on representative Mississippi Delta plantations*

Operation	Mules	Implement	Area per 10-hour day	Cost per 10-hour day	Approximate cost per acre
	Number		Acres		
Flat breaking.....	2	9- to 10-inch plow.....	1.7	\$2.50	\$1.47
Flat disking.....	4	7- to 8-foot single disk.....	12.3	5.00	.41
Bedding 1 furrow, 36- to 42-inch rows.....	2	10- to 12-inch middle buster.....	6.4	2.50	.39
Bedding 2 furrows, 36- to 42-inch rows.....	2	7- to 10-inch plow.....	3.5	2.50	.71
Harrowing beds, 36- to 42-inch rows.....	2	5- to 6-foot drag harrow.....	10.4	2.50	.24
Disking beds, 36- to 42-inch rows.....	2	3- to 4-foot single disk.....	7.3	2.50	.34
Cultivating 1 furrow, 36- to 42-inch rows.....	1	1-mule cultivator.....	5.9	1.25	.21
Cultivating 2 furrows, 36- to 42-inch rows.....	1	do.....	3.1	1.25	.40

In brief, the surveys showed the flexibility and adaptability of various horse and mule hitches, irrespective of the size, shape, or topography of fields, or soil type, and regardless of whether tillage practices called for the speedy or slow completion of a job.

J. O. WILLIAMS and S. R. SPEELMAN,
Bureau of Animal Industry.

INDEX Data on Prices Paid by Farmers Are Now Collected Weekly

Local market prices of articles farmers buy changed rapidly during the third quarter of 1933. During the period from June 15 to September 15, the Department's index of prices paid by farmers for articles purchased advanced from 103 to 116 percent of its pre-war (1910-14) average. This was the most rapid change registered in any 3-month period since the quarterly inquiry on prices farmers pay was first made in 1923.

Evidences of this marked upward adjustment in the cost of products the farmer purchases became apparent long before the next regular quarterly inquiry was due. It became very apparent early in August, that information on prices paid by farmers for articles purchased would have to be collected more frequently if the Department and the newly created Agricultural Adjustment Administration were to keep currently informed as to local market-price movements during that period of swiftly changing economic conditions.

To meet the demand for information, a call was sent to the Crop Reporting Board's regular corps of quarterly price correspondents for volunteers to serve as weekly reporters on the prices farmers pay for a

selected list of articles. Country merchants in every section were asked to report every week on prices of clothing, food, and household articles. Lumber dealers were requested to send in reports of prices farmers pay for lumber, building materials, and fuel. Hardware and implement dealers were asked to supply the Board every week with prices farmers pay for equipment, supplies, and machinery. Feed, seed, and fertilizer dealers were requested to report weekly prices paid by farmers for the commodities they handled. No monetary compensation was offered local merchants for the performance of this service, and the reporters were not urged to cooperate unless it was convenient for them to do so.

The regular price reporters responded willingly to this call. Whereas a maximum of 300 reporters from each group were expected to offer their services voluntarily on a weekly basis, 1,354 usable questionnaires giving data as of August 9 were tabulated on clothing, food, and household articles, and approximately 1,000 returns on an average were received from each of the other groups. The response was a tribute to the public-spirited attitude of this group of American citizens. In fact, it was so generous that it proved impracticable to handle such a large volume of data every 7 days. Since timeliness is one of the most important requisites of a short-time series of data, it was necessary to select from these volunteers a permanent staff of about 200 regular reporters from each group and to solicit these alone for the prices desired. A comparatively small number of reports received each week from correspondents scattered throughout representative sections of the country then proved adequate for the construction of an index of the weekly movements of prices paid by farmers for articles purchased.

The initial spurt in the upward movement of prices farmers pay started early in July. The sharp advance in the wholesale prices of cotton and other commodities handled on the speculative markets caused buyers to anticipate a higher price level, and they rushed to place orders for raw materials for manufacture in the expectation of selling the finished product later at a handsome profit. This enhanced the demand for raw materials and raised their prices.

The nature of the price system is such, however, that these price increases are not confined to any one group of commodities. The effect is like that of a stone thrown into a pool of water. The splash occurs only at the point the stone hits, but the ripples that result spread, with lessening intensity, to the farthestmost corners of the pool. Thus the increased cost of wheat and rising wage rates soon afterward were reflected in an advance in the wholesale price of flour. Then, the country merchant had to replenish his stocks at higher prices and he was forced to charge farmers a higher retail price for flour.

The same sequence of events was repeated in the reflection of higher prices of cotton and rising wage rates in advancing prices of cotton cloth, house dresses, and cotton gloves; and in the reflection of higher prices of other raw materials in the advancing prices charged farmers for other finished goods. Many dealers, however, first disposed of stocks on hand and raised prices paid by farmers only when new orders had to be placed at higher wholesale prices to replenish the supplies on their shelves. Where the farmer purchased feeds and other raw materials direct, the roundabout effect on retail prices was short-circuited, and almost immediately he had to pay higher retail prices for such products. The cumulation of these advances and the after effects of

the speculative rise of all commodity prices in July, resulted in a moderate increase in the general level of prices paid by farmers from August 9 to September 20.

Index of Prices Paid Has New Importance

The construction of index numbers of prices paid by farmers has assumed a new importance to the agricultural industry during the past year. Early in the spring of 1933, interest was centered on the Department's regular quarterly index of prices paid by farmers due to its inclusion in H.R. 3835 (the so-called "Farm Act") as a standard for the determination of fair prices for farm products. Among other things, the avowed purpose of this act was "to relieve the existing national economic emergency by increasing agricultural purchasing power." In section 2 of this act, the policy of Congress was declared to be—

to establish and maintain such balance between the production and consumption of agricultural commodities, and such marketing conditions, therefore, as will re-establish prices to farmers at a level that will give agricultural commodities a purchasing power with respect to articles farmers buy, equivalent to the purchasing power of agricultural commodities in the base period.

This act proclaimed further that—

the base period in the case of all agricultural commodities except tobacco shall be the pre-war period, August 1909–July 1914. In the case of tobacco, the base period shall be the post-war period, August 1919–July 1928.

The index of prices paid by farmers was thus made the measuring stick of fair-exchange values for farm products. If farmers paid prices averaging 116 percent of the pre-war price for the articles they purchased on November 1, 1933, the price received by farmers for wheat on that date should equal the fair-exchange value for wheat, which is equivalent by law to 116 percent of the pre-war local market price of wheat. Since prices received by farmers for wheat and other farm commodities did not approach their fair-exchange value when this act was being drawn up, the Secretary of Agriculture was given power, among other things, in section 8, paragraph 1—

to provide for reduction in the acreage or reduction in the production for market, or both, of any basic agricultural commodity, through agreements with producers or by other voluntary methods, and to provide for rental or benefit payments therewith or upon that part of the production of any basic agricultural commodity required for domestic consumption. * * *

Section 9 of the act provided the levying of processing taxes "to obtain revenue for extraordinary expenses incurred" in this program. Paragraph (D) of this section stated that "the processing tax shall be at such a rate as equals the difference between the current average farm price for the commodity and the fair exchange value of the commodity"; or some fraction thereof, if the full tax would tend to reduce consumption of a particular commodity.

This section makes the fair-exchange value of an agricultural commodity, as figured on the basis of the index of prices farmers pay, a basis for taxation. Although paragraph (C) of this section says that "the current average farm price and the fair exchange value shall be ascertained * * * from available statistics of the Department of Agriculture", it was apparent that current indexes of prices paid by farmers should be available more often than at quarterly intervals for the administration of so important a piece of tax-making legislation. These indexes did not become available until after the processing taxes

on wheat and cotton were announced in 1933, but they doubtless will be employed often for such determination in the future.

Weekly price indexes have enabled the farmer and everyone directly interested in the welfare of agriculture to keep their fingers on the pulse of advancing prices paid by farmers for articles purchased and to combat the practice of exaggerating the extent of necessary price advances. It has enabled the Secretary of Agriculture to follow the adjustments in prices paid by farmers carefully and at frequent intervals. It has been an ever-present indication of changes in the local market price structure. It has provided an implement for comparison with available indexes of prices received by farmers in the measurement of the progress of agricultural recovery.

Limitations of the Index

The national index of prices paid by farmers, with all of its advantages has, however, certain rather definite limitations. Its usefulness is limited by the fact that subindexes are not available for the several geographic divisions of the country. Prices of articles farmers buy do not always advance or decline in all sections of the United States at the same time. Even when an advance or a decline is general the change does not necessarily occur by the same amount or in the same proportion in New England as in the Pacific Coast States. Sectional or even State indexes of prices paid by farmers are desirable and will become necessary if all the facts in the situation are to be uncovered.

Another limitation to the indexes of prices farmers pay is the lack of weekly data during the rapidly shifting panorama of local-market price changes during the period from June 15 to August 9, 1933. The failure to collect data during this period made it necessary to fall back on the June 15 data in computing the processing taxes on wheat and cotton and do not aid in studying the response of retail prices paid by farmers to the advance in prices of the raw materials and in the wages and production costs employed in the manufacture of these products. The continuation of the collection of weekly, biweekly, or monthly series of prices farmers pay will provide many valuable data for such studies in the future, however, and will enable all students of agriculture to keep currently informed of the further progress of agricultural recovery in lieu of only the historical information that was available prior to the inauguration of the weekly price-collecting project on August 23, 1933.

ROGER F. HALE,
Bureau of Agricultural Economics.

IRRIGATION of Weeds and Other Noncrop Plants Costly and Unprofitable

That irrigating weeds is costly and unprofitable is obvious. It is doubtful, however, whether most people realize just how unprofitable it is, especially in the irrigated parts of the country where the value of water is high and conservation of the supply is a prime essential to profitable agriculture. Little attention is paid to weed control or eradication in order to save water, and relatively little investigation has been done to determine a measure of the capacity of weeds as water robbers. The question is: What is the measure of the encroachment of weeds and noncrop plants on the water rights of irrigated crops?

In undertaking to contribute to the answer to this question the Division of Irrigation, Bureau of Agricultural Engineering, has carried on experiments in cooperation with State agencies on the consumptive use of water by weeds and aquatic growths in the last few years in Colorado at Fort Collins, and in California in the Sacramento-San Joaquin Delta and the southern part of the State. The results warrant the statement that in general weeds use more water, in proportion to the ground actually occupied, than do the general run of crops. So if the farmer's weeds do not use more water than his crops, it is because they are not permitted to occupy anywhere near as much ground as the crops.

Experiments Relating to Aquatic Plants

The most striking figures obtained from the experiments relate to aquatic plants, especially the cattail (*Typha latifolia*) and the tule or bulrush (*Scirpus occidentalis*). In the first experiments with these plants they were fully exposed to sun and wind. It was found that the consumptive use of water amounted in the calendar year to from 3 to 5 times as much as on an equal area of alfalfa, one of the heaviest users amongst the crop plants. Later experiments with the same plants set in the interior of areas occupied by the same growths, so as to simulate as closely as possible the conditions of exposure of plants growing on large areas, indicate that under such conditions the consumptive use of water may be only about half as much as when the exposure is extreme. Even so, the water consumed is, acre for acre, four times as much as the average demand of crop plants.

There are numerous other noncrop plants for which figures may be cited. An acre of heavy stand of *Polygonum acre* (which resembles smartweed, and over a large section of the country is known by that name) may consume in a season's growth enough water for the year's irrigation of 3 acres of alfalfa. An area completely taken over by the so-called kelp (*Polygonum amphibium* var. *hartwrightii*) may use twice as much water as alfalfa on the same area would demand. Other plants whose use of water is of about the same order of magnitude as that of kelp are dock (*Rumex* spp.), western golden rod (*Solidago occidentalis*), prickly lettuce (*Lactuca scariola*), cocklebur (*Xanthium canadense*), and nettle (*Urtica gracilis* var.). A thick stand of lambsquarters (*Chenopodium album*) was found to use about 40 percent more water than alfalfa. A mixed growth of volunteer weeds sprouted in June and used in the succeeding 4½ months enough water to have supported alfalfa on the same ground for a year.

These results and others of the same series of experiments have been relied upon in the consideration of the problems arising out of the intrusion of sea water on the Sacramento-San Joaquin Delta.⁵ In estimating consumptive use of water by weeds and aquatic growths account was taken of the conditions of the experiments and of those which surround the plants growing at large. Two principal factors to be taken into account in adapting the results of the experiments are the probable tonnage yield of the weeds and the degree of exposure to sun and wind to which they have been subject. For low-lying or sub-

⁵ CALIFORNIA DEPARTMENT OF PUBLIC WORKS. VARIATION AND CONTROL OF SALINITY IN SACRAMENTO-SAN JOAQUIN DELTA AND UPPER SAN FRANCISCO BAY. Calif. Dept. Pub. Works Bull. 27, pp. 68 et seq.

irrigated idle land bearing various densities of weed growth it was estimated accordingly that 1.82 acre-feet⁶ of water per acre would be consumptively used in one season. Tule areas, including cattails, reeds, and accompanying similar growth, were charged with 9.63 acre-feet per acre. It was also taken into account that weeds growing on fields before planting and after harvest are users of water, and that water-using crops of weeds grow up in fields of sugar beets, corn, and similar crops after cultivation has ceased for the season, especially where subirrigation is practiced. As a summary result, we can deduce, from the figures published, that of the annual consumptive use of water in the delta, amounting to 1,250,000 acre-feet, nearly 300,000 acre-feet, or about 24 percent, goes to sustain plants which serve little or no useful purpose. When the volume of water evaporated from 54,300 acres of open-water surface is subtracted from the total consumptive use in the delta, it appears that of the remainder about 5 parts go to crops and such weeds as grow in the fields with them, and 2 parts to noncrop growths of all kinds which grow apart from the crops.

Similarly, from May to August, inclusive, when the competition of the weeds with crops for water and other elements of plant growth is most clearly real and direct, the weeds and aquatic plants on areas not in crop use each month a little more than one third as much water as is estimated for weeds and crops combined on the cropped area.

Weed Eradication Work Justified

It is not known that similar well-considered estimates of use of water by weeds and noncrop growths have been made for any other region. Such estimates, when made with respect to bodies of land under irrigation, will no doubt show that in general the waste of water in the form of use by weeds and noncrop plants will justify enlargement and intensification of operations aiming at control or eradication of weeds and other intruding growths. It is probable that in only relatively few of them will the figures be as impressive as in the case of the Sacramento-San Joaquin Delta, for there the cropped lands are reclaimed tidal swamp, subirrigation is practiced, ground water is close to ground surface, large areas of tule swamp and open water still remain, and the climate is so mild that it is only in the occasional relatively severe winters that there is not abundant showing of green by native growths even in midwinter. In a majority of irrigated areas there are, nevertheless, conditions favoring the growth of noncrop plants which appropriate a material share of the water for which the farmer pays to serve his crops. Cattails and tules, reeds, water grasses, and other heavy users of water come up on the banks and in the beds of ditches and canals and flourish on seeped areas. In many of these situations the plants are disposed in narrow fringes involving extreme exposure to sun and wind, so that the quantity of water consumed is inordinately great relative to the areas occupied. A stubble field with a high water table, or one which has been flooded soon after harvest, may produce in California with the idea that they aid in preventing erosion by crop plants, or even more.

It may be noted, however, that there are a few items on the credit side of the weed account. A heavy green crop of any of them plowed under is a benefit to the soil, and moreover, some of the weeds are soil

⁶ An acre-foot is 43,560 cubic feet, equivalent to a depth of 1 foot on an acre.

builders. Late-season weeds are encouraged on some hillside orchards in California with the idea that they aid in preventing erosion by winter rains.

Some methods of combating weeds are peculiar to lands served by irrigation. Growths coming up after the harvest of crops may be reduced or prevented by withholding water or lowering the water table, or the seeds may, by the application of water, be made to sprout and then be turned under to the increase of soil fertility and reduction of number of weeds in the next season, and, where frost may be depended upon, still later applications of water will insure that the young sprouts will suffer winter-killing before they have accomplished much damage of any kind. The lining of irrigation channels to prevent loss of water by seepage accomplishes at the same time the eradication of a considerable part of the weed growth.

When weeds mature in irrigated country large numbers of the seeds fall or are blown into the ditches and canals, to be diverted and spread upon the land along with the water, and thus make the battle harder.

The Problem Summarized

Points to be noted by way of summary are:

The conditions of irrigated agriculture include some features which especially favor the growth of weeds and the distribution of weed seeds.

The water consumed on irrigated areas by plants which serve little or no useful purpose costs the farmer, directly and indirectly, proportionately as much as that which he is able to apply to his cropped fields.

The methods used to combat weeds elsewhere may be supplemented and reinforced by expedients available only on areas under irrigation.

Under irrigation, the immediate proximity of weed areas to crop areas is not essential in order that the weeds may rob the crops of water, for they both draw on the same supply which man transports from point to point.

In some cases, as in the instance of the Sacramento-San Joaquin Delta, where intrusion of salt water is accentuated by the extraction of water by cattails, tules, willows, and weeds, the heavy water consumption not only deprives crops of a part of their supply, but also impairs the quality of the supply.

O. V. P. STOUT, *Bureau of Agricultural Engineering.*

LAND Prices in the East and South as Shown by Government Purchases

The last 3 years have witnessed a tremendous shrinkage of values in practically all kinds of property. Although on wild lands the shrinkage has not been so violent as elsewhere, it is but natural that the conditions causing these reductions should be reflected in the average prices paid for cut-over mountain land in the national forests of the Eastern and Southern States in connection with purchase of such lands by the United States under the Weeks law.

It must be borne in mind that the lands so acquired vary greatly in value, both on account of differences in the quality of soil and even more as a result of the presence or absence of merchantable timber.

On the whole, however, the lands may be classed as too poor and steep to support any form of agriculture, too brushy and rough to be primarily valuable for grazing, and usually devoid of enough large-growth timber to warrant any commercial logging operation. As a rule there is little prospect of these lands yielding returns to the owners sufficient to do more than carry the taxes and frequently not even that. Nevertheless, the ingrained desire of most Americans for land ownership, and persistent hopes of being able to sell at high prices to buyers desiring lands for special purposes, have led owners to retain their landholdings for many years in spite of the absence of any real prospects of profit.

Land Purchases from 1920 to 1933

During the period 1920 to 1933 land purchases for national forests in the Eastern and Southern States have aggregated about 2,500,000 acres, acquired at a cost of slightly over \$11,500,000. Considering the lands purchased in all the States together, it is found that from 1920 to 1924, inclusive, the average prices varied between \$3.25 and \$4.50 per acre, and then followed an upward turn to approximately \$4.80 in 1925 and 1926, reaching a peak in 1927 of \$5.60 per acre. In 1928 and 1929 the average descended again to between \$4.50 and \$4.80. From this point the average fell to \$3.60 in 1930, \$3.25 in 1932, and \$2.58 in 1933. The last 1 or 2 years of the period are marked, not only by falling prices but by a tremendous increase in the volume of lands offered, these being several times greater than the amount that could be purchased with available funds.

Prices in New England

There is, of course, considerable variation in prices between the various localities within the region being considered. For example, in Maine, New Hampshire, and Vermont most of the lands purchased have carried much more merchantable timber than is found in other States. During the years 1920 to 1923 inclusive, the lands purchased averaged between \$5 and \$6.75 per acre. From 1924 to 1927, inclusive, a period during which almost any sort of tree growth could be marketed profitably in New England, the prices paid were in excess of \$8.50 per acre, ranging up to \$18 for an especially desirable purchase made in 1926. In 1928 the bulk of the money expended in New England was devoted to the purchase of an unusual tract containing large areas of virgin spruce timber of a character totally different from land ordinarily purchased for national-forest purposes. On account of these unusual features, this tract is disregarded. The average per acre expended for other New England lands in 1928 was \$7 and in 1929, \$7.75. From this point the average prices dropped to \$3.35 in 1930 and \$3.30 in 1931. Only one tract of 200 acres was purchased in 1932. In 1933 a total of 25,832 acres, at an average price of \$4.63 per acre, was approved for purchase. These lands carry considerable timber.

Purchases in Various States

In Virginia and West Virginia, representing on the whole a much lower level of values than those found in New England, the prices varied in the period 1920 to 1924 between a low average of \$2.85 and a high average of \$4.15. This period was followed by a rise in 1925 to

\$4.20 and in 1926 to \$5. The average prices for the period 1928 to 1930 ranged from \$4.30 to \$4.55. A few relatively high priced tracts in 1931 raised the average to \$5.15, but in 1932 offerings were going begging at an average price below \$3.50. In 1933, a total of 16,415 acres, at the average low price of \$2.13 per acre was approved for purchase.

Purchases in Pennsylvania started in 1922 at \$2.75, rising slowly to \$3.60 in 1925. During the period 1927 to 1931 there was wide fluctuation, the low point being \$5.75 and the high, \$8.60. In 1932 such lands as were purchased brought approximately \$3.45 per acre, and lands approved for purchase during 1933 were priced at very little more.

In Georgia and Alabama the prices varied between \$4 and \$5.75 from 1920 until 1925. During the period 1926 to 1929 they rose to a minimum of \$5.25 in 1927 and a maximum of \$5.95 in 1929. Then followed the usual downward curve of \$4.60 in 1930, \$4.05 in 1931 \$3.65 in 1932, and \$3.02 in 1933.

In the Carolinas and Tennessee price averages did not follow the usual curve as indicated by other States, largely because of the fact that during the years 1924 to 1927 very few lands were purchased in North Carolina. Toward the end of the Florida land boom and immediately following its collapse, there was great activity in North Carolina in so-called summer-home and recreational developments. Many tracts were actually sold to private buyers at prices representing far more than their actual worth for forestry purposes. The excessive prices demanded led to an almost complete cessation of Government purchases in that State. Purchases were resumed about 1927, the average prices for that year being \$5.75, followed by \$4.30 in 1928, \$4.25 in 1929, \$4.45 in 1930, \$3.75 to \$4 in 1931 and 1932, and an average of \$3.02 for land approved for purchase in 1933.

In Arkansas a considerable volume of land was purchased in 1920, 1921, and 1922 at prices ranging from \$3.50 to \$3.85 per acre. No lands were purchased in 1923, and in the following 3 years there was a steady increase in the volume and a steady decrease in the average price, which was \$3.09 in 1924, \$2.81 in 1925, and \$2.50 in 1926. Both price and volume purchased per year increased rapidly during the ensuing 3 years, the prices for 1927 averaging \$3.90 and in 1929, \$4.05, during which year over 100,000 acres were purchased. From this point with a continued high volume the prices fell off to \$3.25 in 1930, \$3.05 in 1931, approximately \$3 in 1932, and \$1.92 in 1933.

Lands Purchased Vary Widely in Quality

As already stated, the lands acquired are not uniform in quality or value, and this variation is more than sufficient to account for irregularities and fluctuations in the price trend from year to year. On the whole, however, the prices prevalent during the last 2 or 3 years, together with the great increase in volume of lands offered, indicates a general desire to shift the burden of investments in this class of real estate.

P. J. PAXTON, *Forest Service.*

LUQUILLO National Forest an Important Tropical Forest in Puerto Rico

The Luquillo National Forest in Puerto Rico, proclaimed by President Theodore Roosevelt in 1903, is the only tropical forest in the Federal system.

Located in the Luquillo Mountains, from which it takes its name, in the east-central part of the island, this land, because of its rugged topography and forbidding aspect, escaped being granted to Spanish

subjects for services rendered the Crown prior to the transfer of the island to the United States under the terms of the Treaty of Paris.

The importance of this small forest (13,885 acres at present) is quite out of proportion to its size. Situated at the headwaters of several rivers in a region where rainfall averages around 145 inches annually, its beneficial effects on soil erosion and stream flow are great. It contains the only considerable area of virgin timber remaining in the island, and this may serve both as a natural museum and as a laboratory to develop the best methods of handling similar types elsewhere in the West Indies. From a scenic standpoint, it includes three of the outstanding mountain peaks of the island, the best known of which, El Yunque, 3,496 feet

FIGURE 65.—Portion of Forest Service trail from The Cabin to El Yunque, passing through sierra-palm type. A rock-surfaced trail is necessary to travel on foot as well as with horses.

in elevation, is reached by a graded Forest Service trail (fig. 65).

The forest itself is both beautiful and interesting. It is composed of a great variety of tropical hardwoods, mostly evergreens, perhaps 30 of which are of commercial importance. The more valuable species occur in the coves and on the lower slopes. Above them the sierra palm predominates, and still higher along the ridges, swept constantly by the trade winds, is the dwarf forest. This type is the result of strong winds, heavy rainfall, and high atmospheric humidity. The trees rarely exceed 20 feet in height, the tops being kept at a uniform

level by wind action. Although containing no trees of commercial value, the dwarf forest is tremendously important in an economic way through the protection it affords to the exposed slopes and ridges. It is of scientific interest too because many of the species found there are endemic (fig. 66).

Following the Spanish settlement early in the sixteenth century, the land area of Puerto Rico has been progressively cleared and put into cultivation. Along with the clearing for agricultural purposes went indiscriminate cutting of wood for charcoal and fuel, resulting in the devastation of large areas which will never be cultivated. These lands, to the extent of 400,000 acres or more, are now occupied by worthless brush or poor pastures. Supporting a population of over 1,500,000, or 449 to the square mile, Puerto Rico imports four fifths or more of its wood supply valued at\$ 5,000,000 to \$6,000,000 annually. The insu-

FIGURE 66.—Dwarf rain forest of roble near top of El Yunque, Luquillo National Forest. Trees covered with moss and dripping with water.

lar government recognizes its forestry problem and is making headway in its reforestation projects. Over 1,500,000 tree seedlings are produced annually and distributed free of charge to landowners. Other thousands of trees are planted on insular-forest land.

As at present constituted, the Luquillo National Forest is too small to have much effect on the future timber needs of the island. It does, however, contain a considerable quantity of timber of species valuable for cabinet work and construction purposes. This material will be made available from time to time as additional transportation facilities render it accessible, but the primary objects in the management of this small forest will be (1) to determine and demonstrate the silvicultural practices applicable to the forest types found in the Luquillo Mountains, concerning which little or nothing is known at present; (2) to maintain a forest cover on the steep mountain slopes to assist in controlling stream flow and erosion; and (3) to develop the recreational and aesthetic features of the forest. As one item of this program, a considerable portion of the area will be kept in its original condition, undisturbed by cutting of any kind.

R. M. EVANS, *Forest Service.*

MAGNESIUM Deficiency in Certain Soil Types Reduces Potato Yields

During recent years potato growers in different sections, particularly in States along the Atlantic seaboard, have complained to Department of

Agriculture and experiment station workers that "something is the matter with my potato field." From Aroostook County, Maine, for example, one of the leading table and seed-stock potato-producing sections of the United States, reports emanated in the spring of 1929

to the effect that a "new potato trouble" or "sickness" had shown up in potato fields. An inspection of many potato fields by Federal and State specialists in late June of that season disclosed abnormal foliage symptoms, the most conspicuous of which was a chlorotic condition, there being a marked change in the color of the foliage, from a normal green to varying shades of yellow. The failure of the potato plants to develop their normal green color was associated with the lowest leaves or those formed when the plants were comparatively young.

In severe cases it was observed that the chlorotic condition or yellowing became progressively worse, sometimes involving the entire plant. As a rule, however, mainly

FIGURE 67.—Lack of available magnesium in soil caused breaking down of potato leaf, chiefly at the tips and margins.

the lowermost leaves were affected, the yellowing beginning at the tips and outside margins and later invading the leaf between the veins. Later foliage appeared to "grow out" of the trouble, so far as the yellowing was concerned. It was noted also that there developed a thickening of the leaves with a distinct brittleness, easily detected when crushed in the hand. Latest stages involved a bulging of the leaves between the veins, some rolling of the entire leaf leading to a breaking down of the internal structure with brown dead tissue in evidence (fig. 67). The culmination of the trouble proved to be loss of foliage necessary to starch formation. An examination of the soil where the trouble occurred showed high soil acidity. Yields where the trouble occurred were greatly curtailed.

What appeared to be a similar disturbance was noted several years ago in Suffolk County, N.Y. Yellowing of foliage, stunted growth, and reduced yields were the pronounced effects. Here again the lowermost leaves were affected, later foliage more nearly approaching a normal green color. The soil on which the yellowing first appeared was lighter in texture than the general run of good potato soils in Suffolk County. As the trouble became more pronounced, soils of better quality also were more or less involved. To some extent a similar condition was noted in potato fields in New Jersey, although the yellowing was not so pronounced or so general as observed elsewhere. In New Jersey and on Long Island the trouble was ascribed to excessive soil acidity and to the use of heavy row applications of fertilizer capable of accentuating soil acidity.

Two Types of Injury Disclosed

In the spring of 1931 reports emanated from the Norfolk and Eastern Shore sections of Virginia concerning a so-called potato "trouble". A survey was made of upwards of 60 potato fields; two types of injury were disclosed. The more prevalent type consisted of yellowing or chlorosis of the lower leaves, the upper leaves retaining a more nearly normal color. The plants were affected while relatively young, the yellowing apparently inducing a stunted growth. This condition was particularly noticeable on sandy slopes subject to light washing. Plants growing in low places possessed a much better appearance, having normal color and profuse blooms. The affected plants showed little, if any, blossoming. In fields where manure, green rye, or alfalfa had been turned under there was no sign of the yellowing or stunting. The yellowing of the foliage in Virginia was found to have been most pronounced after a period of relatively low temperature and excessive rainfall, suggesting a retardation of growth on the one hand and, on the other, soil leaching of plant-food constituents, possibly those connected with the formation of chlorophyll, the green coloring matter of plants.

In a majority of the fields examined the soil was quite acid, as was the case in Maine, New Jersey, and Long Island. It was also ascertained that the majority of growers in the different sections on whose farms the trouble occurred had used a fertilizer which, when added to the soil, developed a degree of acidity considerably greater than the soil naturally possessed.

In the use of fertilizer, a ton to the acre being commonly applied for potatoes in the different sections, it was found that the increasing tendency to take advantage of the cheapest sources of nitrogen had led to the inclusion of large amounts of ammonium compounds, chiefly ammonium sulphate, in fertilizer mixtures, which intensified the acidity of the soil close to the roots of the potato plants. Another factor to be considered is the effect of soil acidity on the leaching of basic soil materials, such as lime and magnesia compounds, from the surface soil. This would probably become more marked in the case of magnesium compounds, owing to the fact that fairly large amounts of calcium are applied to the soil if superphosphate is an ingredient of the fertilizer mixture.

Reports concerning the yellowing of potato vines, premature ripening, and reduced yields, have come from other potato-producing sections, which suggest that certain factors might be common to the soil types affected along the Atlantic coast. These factors have been found

to be generally as follows: (1) High soil acidity; (2) use of heavy applications of acid-forming fertilizer applied in the row at time of planting; (3) need of organic matter; (4) leaching effect following heavy rainfall; (5) leached or thinly eroded areas; (6) ineffective liming; and (7) seasonal conditions, chiefly rainfall.

Deficiency of Magnesium Discovered

Investigational work to determine the cause of the trouble showed that some plant-food element associated with chlorophyl formation was deficient in the soil or fertilizer. Field tests have shown clearly that the deficient element was magnesium, as the addition of suitable magnesium compounds to the fertilizer prevented the yellowing and stunted growth. The potato plants in fields so treated were normal in every respect and produced much greater yields than those in the fields receiving the same quantity of fertilizer to which no magnesium compound was added.

During 1932 cooperative field experiments were started on prominent soil types in Maine, New York, New Jersey, and Virginia to determine to what extent magnesium compounds were needed by these soil types. The soil types under study are the Caribou loam in Maine, the Sassafras loam in New York and New Jersey, and the Norfolk sandy loam and Sassafras sandy loam in Virginia.

As a result of these tests it has been definitely shown that some soils in Aroostook County, Maine, are subject to magnesium deficiency. The Maine Agricultural Experiment Station reports increased yields as high as 66 barrels to the acre brought about by the addition of magnesium sulphate to the ordinary 4-8-7 fertilizer. Cooperative tests conducted in 1932 and 1933 afford a further idea of the magnesium requirements of potatoes grown on Caribou loam. While not so marked in 1932, there was in 1933 an increase of 24 bushels because of the application of magnesium in one of the field tests, and in another an increase of 76 bushels. In other tests on Caribou loam the increases were not so significant.

On Long Island and in New Jersey no marked responses have been secured from the use of magnesium and lime compounds in the fertilizer. The practice of making light applications of limestone carrying some magnesium to lower the acidity of the soil has been followed for some time in these potato-growing sections, and this may account for the failure to secure increased yield from the use of magnesium compounds.

In Virginia, on a field of Norfolk sandy loam which was markedly acid, the effect of adding magnesium sulphate to the fertilizer proved highly beneficial, an increased yield of 48 bushels to the acre resulting. On another field of Norfolk sandy loam where the soil was decidedly less acid no significant response from magnesium was obtained.

In magnesium experiments on Sassafras sandy loam in 1932 and 1933 in the vicinity of Cape Charles, Va., application of different magnesium compounds or lime carbonate failed to give significant differences in yield. This can be explained on the basis that dolomitic limestone was applied in the fall of 1931 following the Virginia potato-field survey. It appears in these tests that dolomitic limestone, when finely ground and applied enough in advance, was helpful both in lowering the soil acidity and furnishing enough magnesium for the potato plants.

Chemical analyses of potato foliage, both normal and chlorotic, have shown clearly that the intake of magnesium is much less with the latter. When the magnesium content of potato foliage dropped below 0.15 percent, mild yellowing usually occurred. When the magnesium content registered 0.1 percent and lower, the injury to the plants was serious both in vine growth and yields.

In connection with the magnesium-deficiency studies it will be of interest to refer to figure 68, which shows the regional distribution of magnesium in rivers and lakes over the United States. While an approximation only of the magnesium present and bearing indirectly on the soil relationship, the chart serves to bring out the low content of this element along the Atlantic Coastal Plain, where light soils subject to heavy leaching prevail and where, moreover, magnesium-deficiency troubles have been most prevalent.

There are several ways of adding magnesium to a soil deficient in this element—(1) applying dolomitic limestone to the soil direct, (2) adding

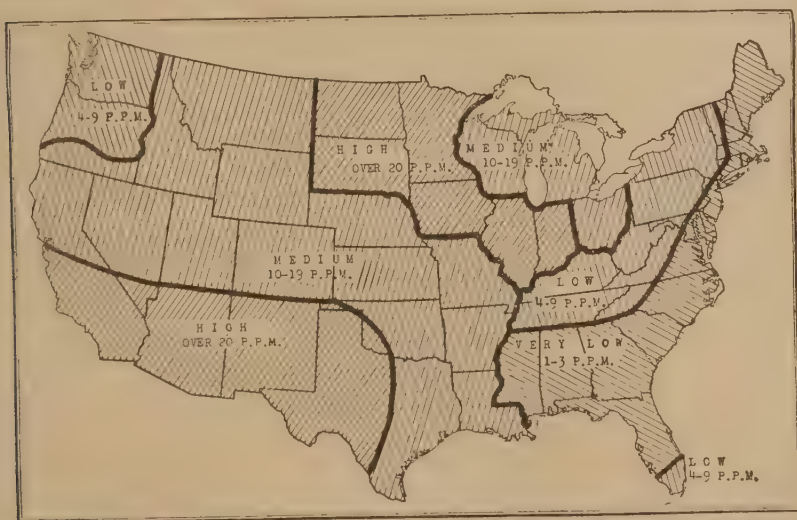

FIGURE 68.—Regional distribution of magnesium in river and lake waters. Based on compilation of analytical data from United States Geological Survey Professional Paper No. 135.

dolomitic limestone to the fertilizer, or (3) adding some quickly available magnesium compound to the fertilizer, such as ordinary or calcined magnesium sulphate, double sulphate of potash-magnesia, or one of the commercial preparations supplying soluble magnesium.

The use of magnesium compounds to correct magnesium deficiency is an important matter for the potato grower and fertilizer manufacturer to consider. Both should be guided not only by the immediate magnesium needs of the potato crop, but more important still they should give serious consideration to a soil-management program which will tend to put the soil in better condition by lowering the acidity of the soil and still avoid any danger from scab. The farmer should increase the organic-matter content of the soil and at the same time make provision for an adequate supply of magnesium for the needs of his crops by using some magnesium in his fertilizer or liming materials.

B. E. BROWN, *Bureau of Chemistry and Soils.*

MARKETING Agreements on Various Crops Increase Returns to the Growers In addition to adopting production-control and benefit-payment programs in connection with so-called "basic crops", the Secretary of Agriculture also has authority under the Agricultural Adjustment Act—

To enter into marketing agreements with processors, associations of producers, and others engaged in the handling, in the current of interstate or foreign commerce of any agricultural commodity or product thereof, after due notice and opportunity for hearing to interested parties.⁷

Thus agricultural industries other than those named as basic, finding themselves with burdensome surpluses, were offered a Federal instrument to assist them in formulating and executing methods of procedure for coping with those surpluses. Marketing agreements pertaining to crops other than those designated as basic are handled by the Special Crops Section of the Agricultural Adjustment Administration.

A marketing agreement as one of the means of accomplishing the purpose of the Agricultural Adjustment Act represents a legal contract between the Secretary of Agriculture and the parties thereto. It binds them to certain methods of procedure in the control of merchantable supplies of a commodity as to prices, trade practices, or other arrangements. In contrast to contracts used in acreage-control programs, growers do not sign marketing agreements as individuals but as "associations of producers." If a grower is also a shipper in interstate or foreign commerce, he may sign as a shipper.

If he deems it advisable, the Secretary of Agriculture may issue licenses in connection with marketing agreements—

Permitting processors, associations of producers, and others to engage in the handling in the current of interstate or foreign commerce of any agricultural commodity or product thereof, or any competing commodity or product thereof.

Licenses are revocable by the Secretary, and penalties are provided for operating without a license. Marketing agreements are not approved until representatives of a very large percentage of the tonnage have signed. When licenses are issued in pursuance of the agreement, they are issued to all handlers involved. It will be noted from the wording of the act, that if a license is issued no one is permitted to operate without it.

The act also authorizes the Secretary to issue licenses without any regard to the existence of marketing agreements. To date (December 1933) this power has not been exercised. Licenses have been issued only as an aid to the enforcement of the terms of marketing agreements. The licensing authority, however, places the Secretary in a position to correct unfair trade practices or charges in a manner similar to that previously authorized for the handlers of perishable agricultural commodities through the Perishable Agricultural Commodities Act.

Object Is Restoration of Farm Purchasing Power

The objective of marketing agreements like the acreage-reduction programs for basic commodities is the restoration of agricultural purchasing power. If a marketing agreement is to be successful in en-

⁷ UNITED STATES STATUTES AT LARGE. AGRICULTURAL ADJUSTMENT ACT. U.S. Statutes at Large 48:31-54. 1933. (73d U.S. Cong., 1st sess., H. R. 3835, par. 2, sec. 8.)

hancing the returns to growers as compared with returns that would otherwise prevail, the agreement must influence economic processes in such a manner as to bring about this result. In the case of the basic commodities, immediate relief is available through benefit payments resulting from processing taxes. The benefit payments are linked to a production-control program designed to reduce the volume of production forthcoming at a subsequent marketing period. Further benefits then accrue through the natural rise in market price.

The benefit-payment plan is not applied in the case of marketing agreements. Benefits through marketing agreements accrue through the influence that their execution exerts upon market price or through fixed or minimum prices stipulated. The principal ways in which returns to growers may be elevated or prevented from falling are three: (1) Reducing the merchantable supply; (2) regulating the market flow of supply either as to time or place; and (3) reducing price spreads between producers and consumers.

No blanket prescription can be applied to all commodities. In each individual case it is necessary to determine what the situation is, why it arose, and why it persists. A marketing agreement drawn for canning peaches should not be expected to be completely applicable to fresh deciduous fruit or to citrus fruit. The price-influencing forces differ in each case because of the difference in the character of the commodities and the manner in which they are handled. Flexibility is one of the outstanding characteristics of the Agricultural Adjustment Act. It does not lay down hard and fast procedure to be followed in all cases. In the case of marketing agreements, no fixed, iron-clad agreement is intended to be applied generally.

It may be well to distinguish between codes and marketing agreements. Codes of fair competition are authorized by the National Industrial Recovery Act for the purpose of eliminating unfair competitive practices, reducing and relieving unemployment, improving standards of labor, promoting the organization of industry for the purpose of cooperative action among trade groups, and otherwise rehabilitating industry and conserving natural resources. A code, therefore, is viewed primarily from the standpoint of its direct effect upon the welfare of the members of an industry, and the laborers engaged in it.

Marketing agreements, on the other hand, are authorized by the Agricultural Adjustment Act, the purpose of which is to improve prices to farmers, and marketing agreements must be examined with the purpose of this act in mind.

An effective marketing agreement cannot be developed purely upon the basis of the fact that the parties to the agreement agree to do certain things. A successful agreement must be predicated upon an analysis of the economic problems faced by an industry. It must include provisions which, when executed, contribute toward the solution of those problems. Commodity price and marketing research on the part of impartial agencies such as the United States Department of Agriculture, the State agricultural colleges, and other research departments is of prime importance. Benefit from restricting the supply of a commodity can accrue only if a small supply will in a given season bring a greater total return than a large supply. A decision as to the extent to which supplies should be restricted is greatly facilitated when price-supply relationships and trends are known. Trends of price-supply relationships reflect long-time influences arising from changes

in consumer buying habits or from changes in the general price level. A knowledge of the degree to which price is affected by the direct competition of other products, and by the export situation, is of vital importance. These are the economic bases upon which marketing agreements must be built.

Human Relationships Involved

Marketing agreements can, however, not be based solely on cold economic consideration; human relationships must be taken into account as well. The interests of growers as producers, growers as cooperative associations, independent shippers or processors, and financial institutions, are frequently quite divergent. Violent clashes between the interests of these groups must be tempered through compromise and a spirit of cooperation toward a common end.

The interests of consumers must be protected. The Agricultural Adjustment Act stipulates that the proportion of the consumer's dollar which is returned to the farmer is not to be increased above the percentage prevailing during the period August 1909 to July 1914. For most crops grower prices represent a small proportion of the prices paid by consumers. Hence the danger of placing an undue burden upon the consumer is not great, provided care is taken to see that the agreements do not widen distributive margins. The Agricultural Adjustment Administration includes a consumer's counsel and all proposed marketing agreements are carefully examined from the standpoint of their effects upon consumers.

TABLE 5.—Marketing agreements entered into in 1933 through the Special Crops Section of the Agricultural Adjustment Administration

⁸ At the request of the Agricultural Adjustment Administration, the canning industry agreed to voluntary price increases to growers. (No licenses issued.)

Source of data: Compiled from records of the Special Crops Section and reports issued by the Bureau of Agricultural Economics of the U.S. Department of Agriculture. (All data subject to minor revision.)

Marketing agreements have been adopted for the following nonbasic crops: Cling peaches canned in California; California deciduous-tree fruits except apples; California Flame Tokay grapes; walnuts grown in California, Oregon, and Washington; Northwest—Washington, Oregon, Idaho, Montana—fresh deciduous-tree fruits; California ripe olives used for canning; and, oranges and grapefruit (3 agreements—1 for California and Arizona, 1 for Florida, and 1 for Texas). Table 5 shows the marketing agreements that have been entered into in 1933 through the Special Crops Section, their effective date, and the approximate volume of the commodity involved in the agreement.

It is too early to evaluate comprehensively the benefits that growers have derived from these agreements. An appraisal of the benefits to growers derived from the cling-peach agreement indicates that because of it returns to growers were increased between \$2,500,000 and \$3,000,000 above that which might reasonably have resulted without the agreement. Information from the fruit districts of the Pacific Northwest indicates that debts are being liquidated, largely as a result of increased benefits accruing from the marketing agreement covering deciduous fruits.

Marketing agreements if properly applied offer an instrument that may be used effectively by many agricultural industries. It is essential that they be drawn and executed on an economically sound basis. In cases where agreements provide fixed prices, a rigid control of supplies marketed is necessary. These agreements are industry programs in which the Agricultural Adjustment Administration acts, until their adoption, in an advisory and coordinating capacity. Following the adoption of an agreement the Administration lends its legal authority toward effective execution.

Because of divergent interests, the formulation and execution of marketing agreements require good local leadership, not only on the part of citizens but also on the part of agricultural colleges and other agencies in a position to make fair appraisals of given situations in given agricultural industries.

In the case of many perishable or semiperishable commodities the problems of restricting the supply marketed or of regulating the time of movement to market are particularly susceptible to handling by means of marketing agreements.

E. W. BRAUN,
Agricultural Adjustment Administration.

MEAT May be Chilled and Cured Successfully in a Home-Made Cooling Box

An ice-chilled meat-curing box that can be made on the farm without skilled labor has been designed by the Department for

use in curing home-dressed meat in the summer or when natural winter temperatures are above 40° F. This equipment can also be used for storing other products that are not affected by a moist atmosphere. The box consists of an insulated outer shell, inside which is a crate for holding the meat. A removable metal cover fits over the top of the crate so that ice can be placed above the meat as well as on both sides. With this arrangement temperatures below 40° F. can be obtained with ice alone (fig. 69).

Temperature control is the most important factor in the successful curing of pork. Bacteria that are present in the tissues of many hogs

at time of slaughter will spoil the meat if they are allowed to grow. Salt is applied to stop the development of these bacteria, but the penetration of the salt into the center of the cuts takes weeks. Low temperatures are the best known means of preventing the multiplication of the bacteria until the salt has had a chance to work into the meat and stop their growth.

Packers chill freshly slaughtered hogs to between 36° and 38° F. within the first 24 hours, if possible. They hold the meat at that tem-

FIGURE 69.—Ice-chilled meat-curing box: A, Perspective view; B, transverse cross section.

perature throughout the curing period. On southern farms such temperatures are not obtainable except through artificial means. Many communities are equipped with commercial ice plants that receive the meat, chill it, and cure it at the temperatures mentioned. Though many localities do not have such facilities, it is usually possible to obtain manufactured ice within hauling distance. Many farmers find it more convenient and less expensive to buy ice to chill and cure their

meat than to utilize the facilities of a commercial cold-storage house. To meet the needs of such farmers, Department specialists designed and tested an ice-chilled box that can be built with farm labor and that will maintain the necessary low temperature throughout the curing period. Summer curing of meat is also practical with this equipment.

Tests of Box Show Effectiveness

In the first test, previously chilled hams, shoulders, loins, and bellies from hogs weighing from 250 to 350 pounds were successfully drycured in the box. Inside temperatures of the box were maintained at 36° F. even though the outside air temperatures ranged from 65° to 90°. Ice consumption was about 1 pound for each pound of meat for the required 40-day curing period.

A second and more severe test included the chilling as well as the curing of the meat. Whole sides of freshly slaughtered hogs weighing from 300 to 400 pounds alive were laid in the crate with wooden strips between them to permit air circulation. At the end of 6 days the internal temperature of the hams and shoulders had dropped from 100° F. to 38° F. The sides were then removed and cut, the curing mixture was applied to the trimmed pieces, and the meat was returned to the box for curing. All this meat was cured and smoked successfully and remained sound during summer storage. Ice consumption in this case was about 2 pounds per pound of meat for the entire chilling and curing process.

Although this unusually severe second test was successful, it is not recommended for general use. In practice the hogs are slaughtered on as cold a day as is available. The carcasses are chilled overnight and cut into pieces for curing. The meat is salted lightly and piled loosely in the ice-chilled box over the second night to cool more thoroughly. On the second day the chilled cuts are given the regular drycure and packed in the box, which is kept iced for the time required to cure meat of that particular weight.

Insulation Should Be Dry

The box consists of a crib of 2 by 4's, with an outer shell of tongue-and-groove flooring, as illustrated. The space between the crib and sheathing is insulated with dry sawdust or shavings. The insulation must be dry. To give more efficient insulation the 2 by 4's should be painted as they are spiked together. This painting, together with an inner lining of galvanized iron, presents a most effective barrier to moisture, the enemy of cold-storage insulation.

In the box shown in figure 69 the floor is insulated with 4 inches of cork, coated with tar and covered with concrete. This more expensive, but more efficient and more permanent, construction has been replaced by sawdust in adaptations of this box designed by several of the State agricultural experiment stations. Meat has been cured successfully in these cheaper boxes, but it should be remembered that the bottom offers the greatest opportunity for loss of refrigeration, and permanently efficient construction must be able to withstand moisture, settling, and warping. For this purpose, cork, tar, and concrete are superior.

It is rarely possible to obtain temperatures below 45° F. when the ice is stored only above the meat. The low temperature of 36°, obtained in this box, was due to the fact that ice was on both sides of the meat as well as above it. Although this arrangement requires more room for

ice and more ice for the original filling, it produces the desired low temperature. If alterations in the design of the icing compartment are made, temperatures under 45° F. will probably be difficult to obtain.

The box illustrated has a capacity of about 1,800 pounds of meat and 1,600 pounds of ice. The length and height of the box may be modified to suit the capacity needed, but the width of the crate should not be increased.

Box Useful for Other Products

In this ice-chilled meat-curing box the humidity of the air is practically at the point of saturation, a fact that should be considered when the box is to be used for other commodities. Chilled fresh meat will become wet and develop surface slime if stored in it for considerable periods. On the other hand, the box is suitable for other food products and many bottled and packaged goods that are not affected by moisture. Ice itself can be held in these boxes for later use with only a small storage loss from melting.

These boxes also afford a dark, insect-proof storage for smoked meat held through the summer at slightly below air temperatures. Although no ice or other refrigeration is needed for holding cured smoked meat, care should be taken to provide some ventilation. Mold will appear on smoked meat so stored, but it should cause no unusual trouble if scrubbed off before the meat is cooked. A complete plan and bill of material for this meat-cooling box, designated by serial no. 2709, may be obtained on request from the United States Department of Agriculture. The material used in the test box cost \$67.

PASTURES Offer Sound Means of Decreasing Feed and Food Surplus In the development of the United States there has been a tendency toward increased production of livestock and livestock products. The methods used have been improved breeding, better methods of feeding, increased acreages of cultivated crops, and farming the land more intensively.

Now with reduced exports and less domestic demand there is need to curtail production. To accomplish this most effectively, a program of reducing the acreage of harvested crops and seeding such land to pasture has been undertaken. This reduces the quantities of feed available for livestock since the yields of most harvested feed crops are nearly twice the yields of the same land in pasture. The program also reduces materially the cost of labor and equipment needed.

The average of 3 years' records on more than 100 farms in central Indiana shows that a 5-year rotation of corn, corn, oats, wheat, and red clover will produce annually about 1,800 pounds per acre of digestible nutrients in the form that crops are ordinarily handled and fed on Corn Belt farms. On the other hand, red clover used for pasture produces about 1,000 pounds of digestible nutrients. The same land in a permanent pasture of bluegrass or a mixture of grasses and legumes will produce even less than can be obtained by pasturing red clover the year following its seeding in oats or wheat. The 5-year rotation of crops requires about 10.2 man-hours, 14.6 horse-hours, or 1.5 tractor-hours per acre annually.

In a similar study of land utilization in southern Indiana, the annual labor requirement for bluegrass pasture was less than 1 man-hour per acre annually. In addition, the erosion from land in the ordinary rotations of feed crops is many times that from pastures. And, on account of the greater yields of harvested feed crops and the fact that they are usually removed from the land, the use of land for pasture is much more favorable to the maintenance of its fertility. Of course, the manure from livestock fed harvested crops may be returned to the soil, but that generally involves considerable labor and waste.

Greater Profits from Farms with Ample Pasture

The above-mentioned study of land utilization in 1928 in southern Indiana, where the land is rolling, shows further that farms having one half of their area in pasture tended to be more profitable than those which have only one fourth of their area in pasture. The increased use of pasture at the expense of corn and similar harvested crops in the more productive areas may not be more profitable to the individual, unless other farmers joined in a program of controlled production.

Such a program of reduced acreage in harvested crops involves less intensive methods of producing livestock. This reversal of policy pre-

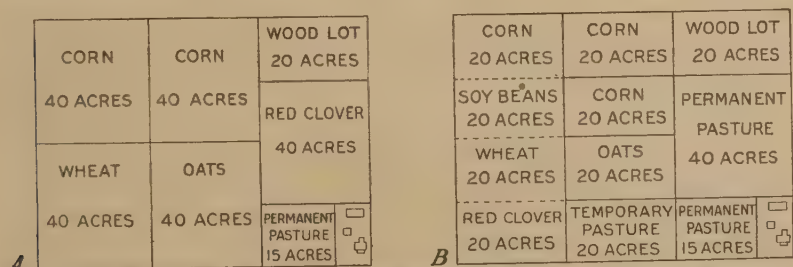

FIGURE 70.—A, Diagram of a 240-acre farm with 200 acres in harvested crops; B, the same farm with 60 acres, or 30 percent, of the harvested-crop acreage seeded to pasture. The crops are shown in fields where they would appear in 1 or more years of each rotation. Fences indicated by solid lines. Dotted lines show unfenced boundaries of fields; fences may be added as needed.

sents many new problems in the management of such pasture lands and livestock.

On farms which have several fields of uniform size in a rotation, it may be necessary, when providing for pasture, to change the rotation or increase the number of fields on the land kept in cultivation. It is usually cheaper and easier to change the rotation than to build new fences. In some cases it may be desirable to use two rotations instead of one by relocating a few fences. A sample farm of 240 acres is used to illustrate how some of the adjustments may be made, since there is infinite variety in the organization of individual farms and no one example can be made to fit all cases. On such a farm, a 5-year rotation of corn, corn, oats, wheat, and red clover on five 40-acre fields could be changed by seeding one of the fields to permanent pasture, and dividing the four remaining forties into 20-acre fields and using a 4-year rotation on each of the two 80-acre tracts (fig. 70).

The new rotations provide for a reduced acreage of grain crops formerly grown and a few new forage crops such as soybeans, sweetclover, lespedeza, and Sudan grass. By having the rotation containing temporary pasture located on land near the permanent pasture and fencing

each 20-acre field, the stalk and stubble fields as well as the temporary pasture can be used conveniently in connection with the permanent pasture. Since the crops in the other rotation of corn, soybeans, wheat, and red clover are all harvested, it should not be necessary to maintain any cross fences on that 80-acre tract. If many sheep are to be kept on the farm the 40-acre permanent pasture may be divided into two or more such pastures so that rotation grazing can be practiced to help in controlling parasites. On a farm where hogs are a major enterprise it is a good plan to have a separate rotation, for the hogs, with one crop, preferably a legume, to be grazed and another such as corn to be hogged down.

Merits of Temporary and Permanent Pastures

Before seeding additional pasture on a farm it is a good plan to consider the advantages and disadvantages of each kind of pasture and

FIGURE 71.—Ewes and their lambs grazing on a temporary pasture of rye sown early in the fall. Such pastures are valuable for extending the grazing season and shortening the winter-feeding period.

plan the rotation accordingly. Temporary pastures produce more, afford greater protection against livestock parasites, fit into rotations readily, and distribute the benefits of grazing animals more uniformly over the whole farm. On the other hand, such pastures require much more labor and seed than permanent pastures, are not so effective in controlling erosion, and are somewhat less dependable than permanent pasture since there is always the risk of not getting a good stand. Generally, it is advisable to have both permanent and temporary pastures. The permanent pasture should furnish most of the grazing, and the temporary one should be such, with respect to size, kind, and time of seeding, that it furnishes plenty of grazing while the permanent pasture is dormant (figs. 71 and 72).

In the Northern States cereals and Italian ryegrass supplement permanent pasture in the spring and fall, while Sudan grass, first-year sweetclover, and lespedeza do the same in midsummer. In the South, vetch, crimson clover, and other legumes as well as cereals lengthen the grazing season in the spring and fall. Southern pastures are not commonly dormant in midsummer.

For permanent pastures, the land most subject to erosion should be selected. Such land is most likely to have a spring or running water

for the stock. Although the land may not always be conveniently located to the farmstead, it is better to build a lane for the stock to use in going to and from the pasture than to crop the rougher land while more level land near the farmstead is in pasture. If such lanes are made from 4 to 6 rods wide, they are much less likely to be barren, weedy, and gullied than if narrow. With a wide lane, one can drive different places to avoid forming deep ruts which favor severe erosion. Another advantage is that fences will need less repair along a wide lane. A lane 4 rods wide and a quarter mile long occupies only 2 acres.

Pastures Reduce Erosion

Taking land out of a rotation of cultivated crops and seeding it to pasture affords an excellent opportunity to stop most of the erosion and gullying which may have been taking place. Rolling land which has a porous subsoil may be level-terraced so that practically all the water which falls is held until it soaks in. These level terraces can be made readily by plowing a furrow and back-furrowing along the contour lines at intervals of from 2 to 3 feet on steep slopes and from 10 to

FIGURE 72. —Beef cattle grazing on Korean lespedeza. This crop, when seeded in small grain in the spring, supplies excellent grazing in July, August, and early September, when bluegrass is short.

12 feet on gentle slopes. Such terraces, which readily become sodded over, not only reduce erosion but increase the moisture content of the soil and aid in keeping the pasture from becoming dormant in dry weather.

On many farms, particularly those of the single-cash-crop areas, such as the Cotton Belt, the establishment of pastures will make it possible to keep a cow or two for milk and to cut down considerably on the feed that must be purchased for the work stock. With the keeping of cows and the use of pasture, new ventures in many cases, it will be advisable to stock up gradually and allow a big margin of pasture and roughage in order to provide plenty of grazing and winter feed. It is well to plan to have at least 5 acres of pasture and 2 or 3 acres of hay for each cow. An excess growth of pasturage the first year makes for a better sod and a more productive pasture.

In the case of farms with several tenants operating on a small scale, one large pasture on which all can keep their cows—or one herd fur-

nishing all with meat and milk—is likely to be much more satisfactory and economical than a separate pasture for each family's cow. Providing similarly for the mules or other work stock should cut the annual cash outlay for feed fully one third in cases where all feed has been purchased.

On livestock farms, where most of the land has been in harvested crops which have been used for fattening feeder stock, the increased acreage of pasture should result in the keeping of more breeding stock or the purchase of feeders at an earlier age. This will necessitate carrying the feeders longer and permitting the use of pasturage in the process.

Creep-feeding may be practiced on good pastures where a single location for shade, water, or both makes it rather certain that the calves will make use of the creep freely. Otherwise, if extra feeding is desired it is usually better to separate the calves and allow them to nurse twice daily. These practices of feeding on pasture mean much in maintaining soil fertility when contrasted with the too common practice of dry-lot feeding on some slope or hillside where most of the fertilizing value of the manure never reaches the cultivated fields.

In order to get the most from pastures with hogs and sheep, parasite problems must be dealt with. If permanent pastures are used by hogs, at least two pastures should be available so that they may be changed from one to another each year. Temporary pastures used only 1 year meet the need for clean pastures in raising hogs. Rotating temporary or permanent pastures will help in controlling parasites of sheep, but drenching is usually necessary to prevent losses on pastures of high carrying capacity. With a few sheep, such as 15 to 20 head, and a farm of several hundred acres the flock may be moved about so as to avoid serious infestation.

Such changes in the farm should result in reduced requirements for labor and equipment, cheaper and more effective maintenance of soil fertility, the production of lighter cuts of meat, and less lard and tallow. The long-time accomplishment should be better returns on account of cheaper production and a reduction of the supply to meet the market needs, provided farmers in general adhere to a program of controlled production.

E. W. SHEETS and A. T. SEMPLE,
Bureau of Animal Industry.

PASTURES Reduce Cost of Producing Livestock and Increase Profits

Pastures if adequate will provide during the grazing season all the roughage that can be profitably utilized by the livestock kept on the farm. The length of the practicable grazing season will depend upon the climate; in the extreme South this period may be year-long; in the North it will vary from 4 to 6 months. Often during the period when weather conditions are such that animals may be outdoors the permanent pastures are more or less unproductive, and some supplemental pasture or supplemental feed, either grain or hay, must be provided during these periods of low production.

Adequate pasturage may be assured by an extensive grazing area or by high production on a limited area (fig. 73). High production may be obtained by the application of fertilizers, the use of better adapted pasture plants, and proper grazing methods.

Meat-Production Costs

In the past the production of beef has centered very largely in the open ranges of the Western States. There, because of the free use or low rental charges of grazing lands, enormous numbers of cattle were produced at low cost, even though it required in some cases 50 acres to support one animal unit for the grazing season of 6 to 9 months. A recent survey of the production costs of range cattle in Nevada shows a long-time average for mixed cattle of 4.36 cents a pound where the ranches were well managed. This, however, allowed for no interest on the investment. Since but little feeding is done in the range country, no direct comparison of this with other methods is possible.

A survey over a period of 5 years of 478 Corn Belt farms engaged in the production of beef calves indicated that the breeding cows were

FIGURE 73.—One of the pastures in southwest Virginia famous for its production of beef cattle. Note how well erosion is controlled on these steep hillsides.

obtaining all of their feed from pastures for an average of 200 days per year at a cost of 4.25 cents a day. During the remaining 165 days when they were maintained on harvested feed the cost was 9.5 cents a day.

At Beltsville, Md., yearling steers with an average initial weight of 556 pounds were grazed at the rate of one head per acre and made an average daily gain of 1.42 pounds for a period of 146 days. This resulted in an average gain of 212 pounds per acre over a period of 5 years, including the drought year of 1930, when the year's gain was less than half the average. No grain or other supplemental feed was given these steers while on the pasture. The cost of the meat thus produced, including an annual pro rata charge for fertilizers, lime, fencing, seed, and seed-bed preparation, and interest and taxes on land valued at \$50 an acre, was only 3.35 cents a pound. These gains were produced on excellent pasture, the annual cost approximating \$7.10

an acre, and only 2 of the 5 years were favorable from the standpoint of rainfall distribution.

Results at both the Mississippi and the Purdue (Indiana) Agricultural Experiment Stations show that if lambs produced on good pasture alone are slaughtered at 4 to 5 months of age they are approximately equal in size and quality to those given a grain supplement in addition to the pasturage.

Experiments at Ardmore, S.Dak., conducted by the Bureau of Animal Industry, indicate that hogs on good pasture such as alfalfa require about 10 percent less of concentrates per pound of gain and that the need for tankage is reduced one third. A recent survey by the Illinois College of Agriculture of 43 farms shows that proper methods of swine sanitation involving the use of clean pastures not only produced healthy pigs but saved 11 percent of the feed. In Ohio it was found that pigs fed while on pasture made a daily gain of 1.2 pounds and consumed only 344 pounds of corn for each 100 pounds of gain, while those fed in a dry lot gained only 0.67 pound per day and consumed 508 pounds of corn for each 100 pounds of gain. Pastures of alfalfa or other legumes or of rape are best for hogs. In South Carolina hogs fed corn and fishmeal made larger daily gains when fed on soybean pasture, and the profit per hog on pasture was \$1.86 as compared with \$1.25 in the dry lot.

Milk-Production Costs

Farm surveys in six counties of New York covering a period of 3 years showed that the daily expense for feed while the cows were on

pasture was 9.7 cents and while in the barn 38 cents. In a survey of land utilization in southern Indiana in 1929 it was found that pasture furnished feed at one fourth the cost of harvested feed. Notwithstanding the fact that these were poor pastures requiring an average of 3.4 acres per head to carry a mature cow for the 6-month grazing season, the average cost of pasturing a cow was 5.57 cents a day.

FIGURE 74. — A normal production curve of permanent pastures in the Corn Belt, illustrating the use of supplemental pastures to lengthen the grazing season and provide sufficient feed for the farm livestock from April 15 to October 14. Either Sudan grass, Korean lespedeza, or soybeans may be used in late summer and fall. The sweetclover should be grown in a rotation with corn and wheat. The first-year crop should be harvested for hay; and the second-year growth, after being pastured in the spring, may be plowed under May 1 in preparation for planting corn.

In Oregon on irrigated pastures of ladino clover, where the carrying capacity was 3 cows per acre instead of 3 acres per cow as in southern Indiana, the cost per acre of pasture was much higher, and supplemental feed, both grain and hay, was given to the cows while they were on pasture. The feed cost (pasture plus supplements) per 100 pounds of milk produced was 91 cents, as compared with a feed cost of \$1.20 per hundredweight of milk in the barn. The net return from the pasture was \$41.01 per acre.

These are only a few of the many results that demonstrate the usefulness of pastures in the production of meat and milk. If, then, ample

pastures tend to reduce the cost of livestock products and increase farm profits, it is obvious that more pasture and more attention to methods of lengthening the grazing season are justified. The farm survey in southern Indiana plainly indicates that, under present conditions, farms that are half in pasture and half in cultivated crops are more profitable than those with only one fourth their area devoted to pastures. The application of reasonable quantities of fertilizer will increase the productiveness of pastures, and the use of supplemental pastures, as shown in figure 74, will extend the period during which farm livestock may obtain their feed requirements by grazing. Both methods are worthy of full consideration as measures of relief from the present depression in agriculture.

Bureau of Plant Industry.

PATTERN of Real Estate Values Less Changed Than Level of Values

Farm real estate derives its value from its capacity to yield goods or services which command a price. Generally speaking, such values are high where the value of the per acre yield is relatively high, and low where the converse is true. A relatively high value of acre yield may result from high physical productivity, from an especially favorable location with respect to market, or from some combination of the two. In the United States the development and interplay of physical and economic factors over a long period have resulted in a more or less definite pattern of farm real estate values.

This generalized pattern is evident in figure 75, in which each county is shaded according to the average value per acre of such agricultural land as it may contain. The areas of high value per acre are concentrated principally in the Middle West, in certain parts of the Pacific coast, in Florida, and along the Atlantic coast of the Middle Atlantic and southern New England States. Isolated areas appear also in the neighborhood of many of the principal cities.

The general pattern in 1930 was similar to those of 1925, 1920, and even 1910, even though the average level of values fluctuated drastically from period to period. The average value per acre of farm land and buildings the country over was \$39.60 in 1910, \$69.38 in 1920, \$53.52 in 1925, and \$48.52 in 1930, according to the Bureau of the Census. Since 1930, land values in nearly every agricultural region have declined drastically. These changes in levels have been due primarily to economic factors, principally changing prices, whereas the general pattern of values, which has remained more constant, had its origin, to a large extent, in physical differences of productivity and location with respect to markets.

Although the pattern of values the country over has remained somewhat the same, there has been considerable variation in the relative change between areas from time to time. In other words, the pattern, though it has retained the same general outlines, has changed in practically all its details. For example, the average value of farm land in the Corn Belt has been higher than that in the Cotton Belt for many years, but the changes in values from year to year or from decade to decade have been far from equal. Even within areas, changes have not been uniform.

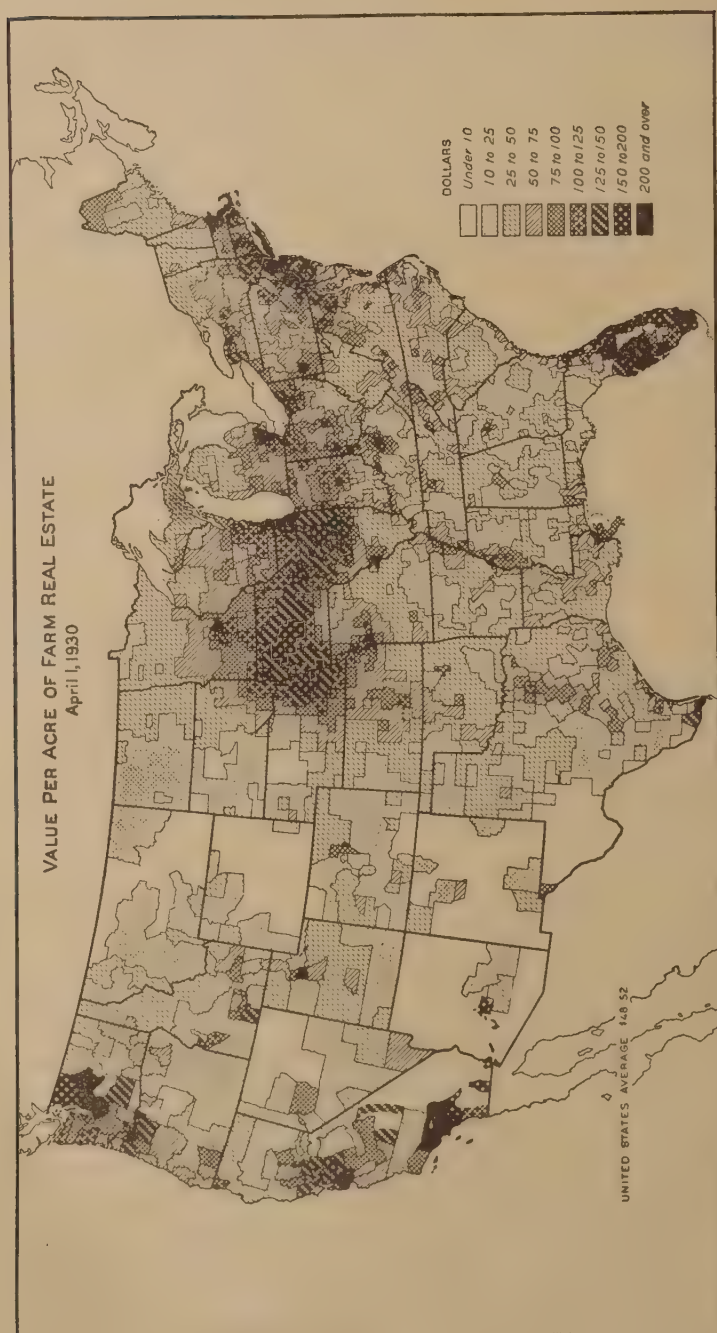

FIGURE 75.— Areas of high value per acre are found along the southern coast of the North Atlantic States, near large cities, in the Corn Belt, in fertile valleys, and in other areas especially favored by local circumstances. Large areas of low-priced land are found in the Mountain States. Between these two extremes is great variation, depending upon the combination of physical and economic factors peculiar to each locality.

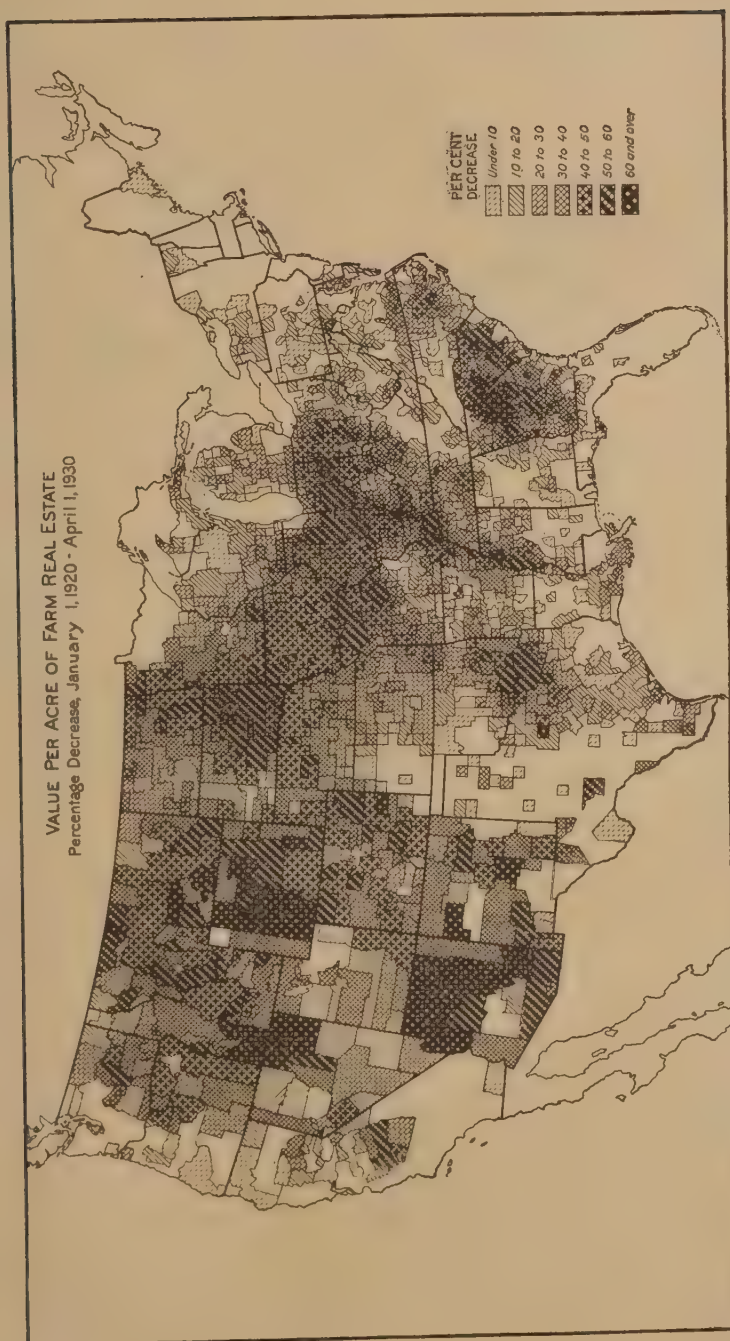

FIGURE 76. - Although farm real estate values in 1930 in general were lower than in 1920, the changes were far from uniform. There were significant differences between geographic areas, even within States, as well as between farms of different size and different value.

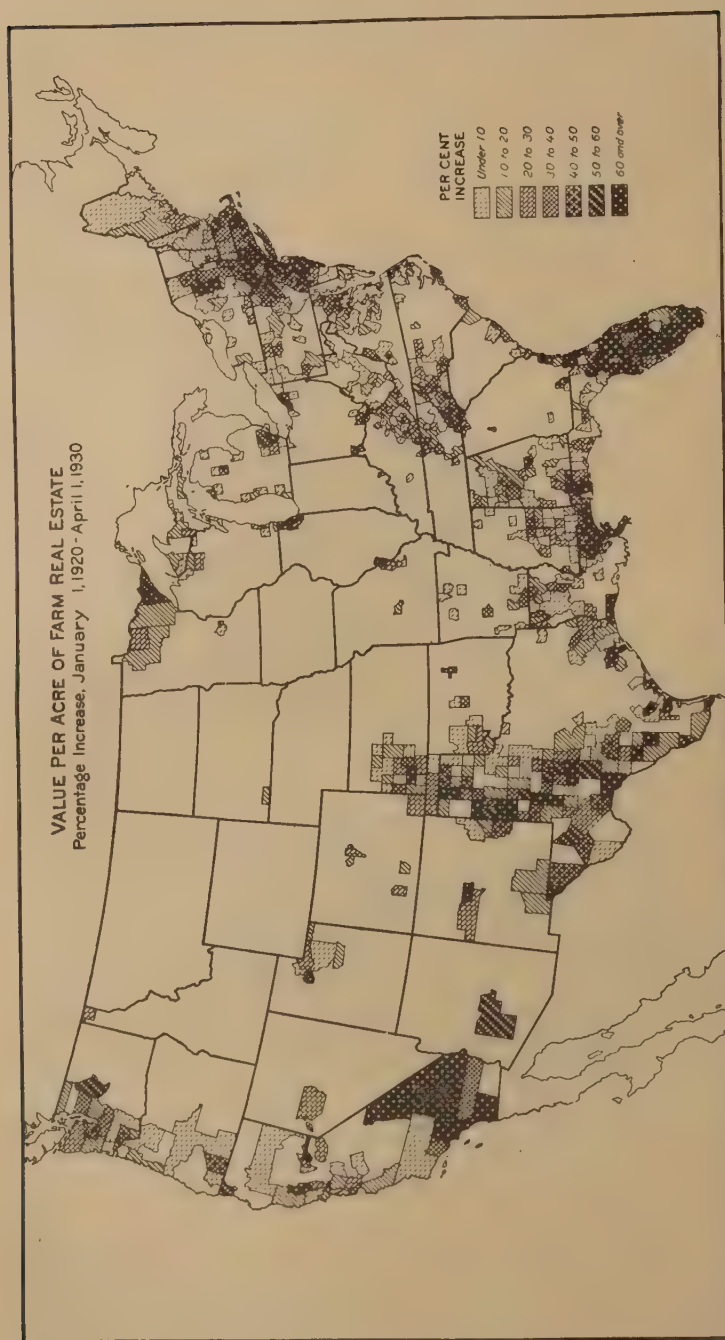

FIGURE 77.—Although the trend of farm real estate values was in general downward from 1920 to 1930, there were limited areas where values apparently increased. Shifts in farming areas, the influence of growing cities, and the development of new irrigation areas are among the local factors having significant effects upon land values.

Certain of these differences are readily apparent if the relative changes in value between two periods are compared, as, for illustration, in figures 76 and 77, where each county has been shaded according to the relative change in value in its real estate between January 1, 1920, and April 1, 1930.

Variations From Main Trend, 1920-30

As is generally recognized, the decade 1920-30 on the whole was a trying one for agriculture. The average value per acre of all farm real estate was roughly one third lower at the end of the decade than at the beginning. Yet there were substantial areas in which average farm real estate values were higher in 1930 than in 1920. The predominant trend was evidently decidedly downward, but substantial sections of New England and other Eastern seaboard States, parts of the Pacific coast, and of the South, particularly western Texas, as well as several other scattered areas, experienced increasing values.

In the North Atlantic States, the important factors involved are generally recognized, namely a concentrated and growing market for food products, expanding suburban residential areas, increasing emphasis upon specialty crops, and abandonment of lower grade and inaccessible farms.

In western Texas, Oklahoma, and Kansas, the transition from a less intensive to a more intensive use, through the expansion of wheat and cotton to the parts of these areas to which they are respectively adapted, has been largely responsible for the higher average values there.

The higher acre values in Louisiana, Mississippi, and Alabama are probably partly nominal, the result of certain changes that were made in the procedure of the census enumeration. It is probable, however, that part of the differences in the average value of real estate indicated by the census between Mississippi and Alabama, on the one hand, and Georgia and South Carolina, on the other, has real significance. High prices, the bollweevil, and depression, appeared in what was apparently a more unfortunate sequence than occurred farther west.

Several more-or-less isolated areas of increasing values appear in the neighborhood of several of the larger cities throughout the country. Adjacency to large cities means that farm land in the neighborhood is subjected to the combined influences of expanding suburban or residential areas, expanding requirements for industrial or commercial sites, as well as to the increasing opportunity for producing for a specialized, highly concentrated local market.

In the vicinity of the larger cities there is thus a combination of both agricultural and nonagricultural factors tending toward higher values. The more direct effects of nonagricultural factors may perhaps be more easily seen by considering separately on the one hand the average value of farm land in those counties parts of which are included in the metropolitan areas as described by the census, and on the other, average values in the other counties.

Although much land in the vicinity of cities is farmed, and enumerated by the census as land in farms, it is often held at values considerably in excess of its value for strictly agricultural purposes, because owners anticipate appreciation on account of possible residential or industrial use.

In nearly every State in which there were metropolitan areas as defined by the census, the average value of farm real estate was greater in

those counties which lay partly or entirely within a metropolitan area, than in those counties lying wholly without such an area. In most instances, the differences were considerable. Except in the Northeastern States, however, the area of farm land in the metropolitan areas was so small, relative to the State total, that its exclusion usually made only a few dollars' difference in the State average, but in most States of the Northeast as far west as Ohio and as far south as Maryland, exclusion of such farm land reduced the State average appreciably.

Differences in Rate of Change of Values

More significant, however, are the differences in the rate of change of values. The decade 1910 to 1920 was one of rapid increase in average value in practically all regions. In many States, particularly in the Middle West and South, farm real estate in counties wholly outside metropolitan areas increased more rapidly in value than in other counties.

The next decade, as is well known, was unfavorable to agriculture, and in nearly all areas land valued for agricultural purposes declined in value far more than that in the vicinity of cities. In fact, value per acre of farm real estate in many of the counties lying partially within metropolitan areas increased markedly during the decade.

In Ohio the increase in average value per acre of all farm real estate from 1910 to 1930 was about 15 percent, but excluding counties on the basis indicated, the average increase of the remainder of the State was only 7 percent. In Indiana exclusion of the counties indicated alters the average change from a decrease of 4 percent to a decrease of 6 percent. In Michigan the average change is reduced from an increase of 42 percent to 33 percent, and in California it is changed from an increase of 116 percent to an increase of 98 percent.

In Wisconsin, and in most of the West North Central, Southern, and Western States, the differences in relative change are of less importance.

Farms of Different Sizes Unequally Affected

Not only do changing economic conditions bring about different results in different localities, but they also affect unequally farms of different sizes within the same general area. Farms very much larger than the typical farm usually differ in essential features of their organization from the typical farm. They are likely, therefore, to be affected by economic changes to a different degree, or even in a different direction, than the typical farm. Small farms, for example, often tend toward the truck or poultry type, whereas large farms often tend more toward livestock enterprises. Obviously, since prices of different groups of farm products do not usually change together, and since considerable shifts in farm organization cannot usually be accomplished at once, it may be expected that in general value of farms of different sizes will change at different rates.

For the United States as a whole the average value per acre of farm land and buildings, as reported by the census, increased 75 percent from 1910 to 1920, and then decreased 30 percent during the following decade, leaving a net increase of 23 percent over the 20 years. For farms under 20 acres in size, however, the net change for the period was an 85 percent increase, and for farms of 1,000 acres or over, the net increase was only 3 percent.

If the average size of farm may be considered as the typical farm, it may be said that in general terms the typical farm apparently experienced greater relative increases in value from 1910 to 1920 than did the other sizes, and experienced decreases about in proportion to all farms in the following decade, making the net increase from 1910 to 1930 somewhat greater than the average of all farms.

Averages for the whole United States are highly generalized. A better, but not altogether satisfactory, unit for consideration consists of the customary geographic division, but even here generalization is difficult.

Small Farms Fared Better than Average

One statement can be made definitely. Small farms appear to have fared better than the average. In every geographic division there has been, for farms under 20 acres in size, a net increase in value per acre from 1910 to 1930. In no area has the increase for all farm land been so great as for the small farms, and in one area (the Mountain States) the average for all farms has decreased, partly by reason of the inclusion in farms of more low-grade land in the later period.

With the exception of the very small farms, there appears to be a tendency in the North Central States for the size groups that increased most in the boom years to have decreased most in the readjustment period. It cannot be said, however, that these groups fell lower, relative to 1910, than the groups that experienced small increases.

Not only have there been differences in the relative changes in values for different-sized farms, but there have also been differences between counties of high and of low average value per acre, even within geographic divisions. A classification of counties on the basis of their average value per acre of farm real estate in 1910, and a comparison of the relative changes in value for several periods reveal certain interesting relations.

The summary for the United States indicates that, with the exception of the few counties in which farm real estate was valued at over \$150 per acre in 1910, the lower valued lands have increased more, relative to their 1910 value, than have the higher valued lands. Thus, in counties where real estate was valued at less than \$10 per acre in 1910, values have a little more than doubled during the 20 years, whereas, for higher valued lands the relative increases were progressively smaller (with one exception). However, a 100-percent increase on \$10 land is only \$10, whereas a 30-percent increase on \$100 land is \$30, or three times as great. Hence, although the lands with lower initial value increased the most relatively, the absolute increases were in general greater for the medium and higher priced lands.

Counties reporting values of \$200 or more per acre in 1910 were so located that they cannot be considered as reflecting predominantly the effects of agricultural factors. In fact, practically all of the counties in the group either contained sizable cities or constituted the outlying part of a large metropolitan area. For purposes of the present discussion, this group can be ruled out as not representative of typical agricultural conditions.

Variation Among Size Groups

Considerable variation was evident from one size group to another, and from one area to another. In several of the geographic divisions, as for the United States as a whole, the counties with the lowest valued

real estate increased in value more, relatively, than have the other groups. Land valued at less than \$10 per acre in 1910 frequently was land in a low stage of development. The addition of improvements and the fact that an increase of only a few dollars constituted a large percent increase when the base is less than \$10, probably mainly explain these large increases.

Excepting the extreme high- and low-value groups, there appears to be a tendency in certain areas, and with certain exceptions, for the groups that experienced the greatest relative increases from 1910 to 1920 to have fallen the most from 1920 to 1930.

In the East North Central States, for example, the \$125-to-\$200-per-acre farms increased more than most other groups, fell further on an average, and ended the 20-year period considerably lower relative to the 1910 value, than was the case with the other groups.

In the West North Central States the \$50-to-\$125-per-acre farms, as a rule, increased more, subsequently declined further, and ended the 20 years lower, relative to their value in 1910, than did most of the other groups. In the South Atlantic region the \$10-to-\$75-per-acre farms rose more rapidly in value. Over the 1910-to-1930 period, however, these groups showed a smaller increase in value than did the average of all counties in these States. A somewhat similar situation is indicated in the East South Central section, but does not appear so clearly in the West South Central. In the latter group particularly, the more valuable farm land appears to have experienced the least relative increase in value.

These generalizations refer to regions, and not to individual farms. The distinction is significant, for a change in the enumerated acreage within a region may alter the average for a region even though the value of individual farms undergoes no change.

The variations that have been cited serve to illustrate the fact that a change in average value per acre for the country as a whole merely represents the sum total of the currents and cross currents that affect the various localities making up the whole. Accordingly, a national or regional average may be reasonably interpreted only as a measure of net effect, in a certain sense, but not as an accurate reflection of situations in particular localities.

B. R. STAUBER,

Bureau of Agricultural Economics.

PINK-BOLLWORM Outbreak Fought by Destroying Wild Cotton in Florida The wild cotton of Florida is a true *Gossypium*, the stalks, leaves, blooms, and bolls having all the general appearance of cultivated cotton. The bolls are very small, usually with three locks, the lint being very short and of no commercial value. It is very probably a native of this locality, and sometimes makes good-sized trees, some reaching a height and limb spread of 15 to 20 feet, with a diameter of 4 to 6 inches. Because of the tropical climate the plants fruit almost continuously.

The southern end of Florida is in general a very low-lying country, the highest points being only a few feet above sea level. Near the coast the land becomes imperceptibly lower, and offers very poor drainage, which condition results in numerous islands surrounded by shal-

low water, many parts of them being covered during high tide. In the main these islands (or keys, as they are called in Florida), as well as the mainland, are covered with an almost impenetrable growth of subtropical plants, so that in order to get through these jungles it is oftentimes necessary to cut one's way with a machete.

Wild cotton in its natural state has only been found on the keys and near the coast on the mainland. As a rule there is a heavy growth of mangroves along the edge of the keys and mainland, and cotton, if present, usually occurs in a strip between the mangroves and the hammocks, which are composed of a dense growth of various plants. Many of the keys seem to have been inhabited in past ages by Indians who are thought to have made the numerous oyster-shell mounds which occur. Cotton oftentimes grows on these shell mounds.

The pink bollworm was discovered in southern Florida in June 1932, the initial infestation being located in small plots of cultivated cotton totaling approximately 2 acres, at the United States Plant Introduction Gardens at Chapman Field, near Miami. It was soon found that the wild cotton was generally infested. This wild cotton was found to extend from Miami to Key West, being most abundant from a point some 70 miles below Miami to the southern end of Lower Matecumbe Key, a distance of 25 to 30 miles. All of the cotton in this strip was infested. A considerable amount of infested wild cotton was also found on the mainland, near Flamingo, on Cape Sable.

The eradication of the infestation at Chapman Field was a comparatively simple matter; however, the wild cotton presented a much more serious problem. Its general distribution and the degree of infestation had not been determined; consequently it was not known at that time whether or not it would be physically possible to eradicate all of it from the State. It was perfectly evident, however, that it would be practicable to destroy all of that growing along the highways and in other easily accessible places so as to eliminate any danger of tourists or other travelers distributing the insect to new localities. This work was immediately begun, and was soon completed to the extent that one could pass through the area without finding any wild cotton unless at special pains to look for it.

Distribution of Wild Cotton

The next step was to conduct a thorough survey to determine as accurately as possible the exact distribution of the wild cotton; also, the extent of infestation. In making part of this survey it was necessary to charter a cabin launch to reach long stretches of inaccessible coastlines and numerous keys where considerable open water had to be crossed. A portable boat outfit consisting of a 12-foot skiff with outboard motor and trailer was used to advantage in less exposed locations. On the east coast the only wild cotton found above Miami consisted of four small colonies near the town of Grant, in Brevard County. On the west coast it occurred rather generally on the mainland and adjacent keys from Cape Sable northward to St. Petersburg. Only one small colony was located above this point on a small key near Hudson, in Pasco County. In no case was wild cotton found growing any great distance from the coast. This left a distance of only 150 miles between wild cotton and the commercial plantings of northern Florida. Sufficient inspecting was done to determine the fact that a considerable part of this wild cotton along the west coast was

infested, the most northerly being on Terra Ceia Island, in Manatee County. On the east coast only one infestation was found above Miami, this being on dooryard cotton plants at Lake Worth, in Palm Beach County. The survey indicated that it would be possible and practicable to eradicate the wild cotton from southern Florida and adjacent keys.

There are in general two seasons in southern Florida. In the late spring, summer, and early fall comes the wet season, and in the winter and early spring occurs the dry season. During all parts of the wet season much of the land is covered with water, and the areas are seriously infested with mosquitoes, which makes work practically impossible. Because of this condition the eradication was not begun until the latter part of November 1932. The experience gathered while eradicating plants from the roadside in the early summer demonstrated that it was necessary to remove all of the roots; otherwise they would put out sprouts. It was therefore necessary to go over the area which had previously been cleaned to remove these sprout plants and also seedlings, which had come up in the meantime. By "seedling" plants is meant those up to the size of walking canes; plants any larger than this are considered mature. All of the wild cotton on the east coast was removed.

On the west coast it was evident that it would be impossible to go over the entire area before the rainy season set in; therefore the area from Naples northward was cleaned. This increased the distance between commercial plantings and the wild cotton by 150 miles, making a total separation of some 300 miles. All of the accessible cotton on Cape Sable was also removed, together with much of that in the more inaccessible locations.

During this eradication campaign some 625,000 mature, 816,000 seedling, and 19,000 sprout plants were destroyed. Many wild and domestic cotton plants are grown in yards as ornamentals, and these have also been destroyed. With only 1 or 2 exceptions the owners very readily agreed to have such plants destroyed after the danger had been explained to them. It is planned to resume this eradication campaign during the next dry season.

Experiments with Chemicals

In connection with the program some preliminary experiments were carried on to determine the feasibility of killing wild cotton with chemicals. Sodium arsenite solution seemed to give the best results. Where this solution was sprayed on the plants, however, they merely shed their leaves and began putting out new growth. In other cases the solution was poured around the base and roots of the plant, but they were not killed unless the base of the plant was bruised in some manner before the solution was applied. Further experiments are necessary in this connection before any definite conclusions can be reached.

A number of difficulties have been experienced in this work. On account of the locations in which wild cotton grows, it was often necessary to work many miles from a base of supplies. For example, in the Cape Sable clean-up all supplies, including drinking water, had to be hauled for a distance of over 40 miles, part of which was over very bad roads. Of course, boats had to be used to reach the keys, and even so, it was necessary for the men to wade considerable dis-

tances in many cases. There were also insects to contend with, especially mosquitoes, and occasionally poisonous plants. Rattlesnakes are very numerous in that part of the State, and almost every day during the clean-up one or more were killed. In spite of all these difficulties the work progressed especially well. There is still considerable wild cotton in the more isolated localities to be destroyed; however, the work done thus far indicates that it will be possible and practicable to eradicate wild cotton in southern Florida, and thereby eliminate the present pink-bollworm outbreak there and prevent the establishment of new infestations on the keys and along the coast.

R. E. McDONALD, *Bureau of Plant Quarantine.*

PLANT Breeders Make Progress in Developing Disease-Resistant Corn Quality in corn is evaluated generally in commercial channels by the application of the Federal grain standards. Corn meeting the requirements for grades

No. 1 and No. 2, and sometimes No. 3, is considered high in quality. Corn grading No. 5, No. 6, and Sample is usually acknowledged to be low in quality.

The two most important single factors in determining numerical grade or commercial quality at the present time are moisture and total damage. During the 9-year period 1923-24 to 1931-32, according to data gathered by the Bureau of Agricultural Economics from supervised inspections of corn receipts at all inspection points in the United States—

approximately 33 percent of the market receipts of the average crop of corn had their grade determined as lower than grade No. 1 because of the factor "total damage" under the present official standards.⁸

The ear and kernel-rot diseases (fig. 78) are very largely responsible for the damaged corn referred to in the grade factor "total damage." These diseases are also known as the "dry rots" of corn. Most lots of market corn carry a considerable quantity of slightly diseased kernels that are not sufficiently rotted to be classed as damaged. When such lots of corn have a rather high moisture content, the amount of badly rotted and damaged corn increases rapidly in storage and transit. Other things being equal, lots of corn comparatively free from these dry-rot infections are likely to retain their grade and quality much better in storage and transit than lots of corn that carry a high percentage of such infections, even though the infections may not be sufficiently developed to cause the corn to be classed as damaged.

Completely rotted ears that are left in the field or thrown out at the dump have little or no value. They subtract from the yield and add to the cost of production. Ears from plants weakened by disease are very likely to be chaffy or light in weight. When corn harvesting is delayed on account of unfavorable weather, the amount of partly rotted and weather-damaged corn from down and broken stalks frequently increases to a point where the feeding value and keeping qualities are materially lowered. Thus, the corn-disease problem is directly concerned with both the quality of corn marketed and that used on the farm.

⁸ UNITED STATES DEPARTMENT OF AGRICULTURE, BUREAU OF AGRICULTURAL ECONOMICS. PROPOSED REVISED FEDERAL GRAIN STANDARDS, INCLUDING EXPLANATIONS. U.S. Dept. Agr. Misc. Pub. 173: 82. 1933.

Developing Disease-Resistant Strains

The most effective method that has been found for controlling diseases that lower the quality of corn is the development and use of disease-resistant hybrid strains resulting from the crossing of disease-

FIGURE 78.—A, Unloading corn by a horse-driven dump. Conspicuously rotted ears are being thrown out to improve the keeping quality of the corn in the crib. If such ears were allowed to go into the crib they might cause much additional damage during storage, thus lowering the market grade and feeding value of the corn.

B and C, Ears badly rotted by *Diplodia*, one of the most important of the dry-rot diseases.

D and E, Chaffy ears. The same fungus that causes *Diplodia* ear rot also causes *Diplodia* stalk rot. Plants with stalks badly rotted prior to maturity frequently produce chaffy ears and corn inferior in quality.

F, a, Sound ear; b, an ear apparently sound as judged by outside appearances, but heavily infected with *Diplodia*. These inconspicuous infections often develop in disease-susceptible strains during a period of warm, wet weather following maturity and prior to the time the corn is harvested. They also may develop in storage in the crib. The grain from such ears materially lowers the grade and quality of the corn for market purposes as well as for feeding livestock on the farm.

G, Enlargement of kernels from the two ears pictured in F.

H and I, Shelled grain from a disease-susceptible and from a disease-resistant hybrid strain of corn, respectively, harvested near the end of the corn-harvesting period, the middle of December (1932), following a prolonged period of weather unfavorable for corn harvesting. During this period approximately 20 percent of the grain in several disease-susceptible strains was damaged by disease, similar to that shown on the right in G. Under the same conditions, less than 2 percent of the grain of the disease-resistant strains was damaged. The total yields of the two groups of hybrid strains were practically the same but the difference in quality was very marked.

resistant inbred lines. The expression of disease resistance in corn is influenced by a number of conditions, such as crop rotation, soil fertility, drought and heat injury in the summer, cold injury in the fall, and insect injury. Moreover, disease-resistant strains, to be useful, must also have other desirable qualities combined with their disease resist-

ance, especially the capacity to produce a satisfactory yield of well-matured grain on stalks that stand up well until the corn is harvested.

Complicated as the problem of developing disease-resistant strains for different sections is, very encouraging progress has been made by a number of workers throughout the Corn Belt. It seems reasonable, therefore, in the light of what has been accomplished in the last few years, to predict that within the not-far-distant future strains of corn that combine disease resistance with other necessary and desirable qualities will be developed and made available for distribution.

J. R. HOLBERT, *Bureau of Plant Industry.*

PLANT-DISEASE Control The cornerstone of an effectively
Important in Efforts planned utilization of our agricul-
to Regulate Production tural land is adequate control of
production. A common reason for
overplanting is the chance that one will make money by someone else's
failure. Overplanting too often results in overproduction and disaster.
On the other hand, with certain crops, yields and prices have fluctuated
so greatly that even a crop from poor land occasionally proved profit-
able. But for these occasional profits such "speculative planting"
would largely cease, and many such submarginal lands would be volun-
tarily withdrawn from cultivation.

An important factor in the fluctuation of agricultural crops is the loss from plant disease. Crop losses from plant diseases vary greatly and are as yet almost unpredictable. For example, losses from brown rot in Georgia peaches dropped from 40 percent in 1920 to 15 percent in 1921 and to 5 percent in 1922. In 1927 the loss was estimated at 20 percent, and in 1929 it was back to 5 percent. In 1932 downy mildew of tobacco, which had been observed in this country only twice before, proved so serious in Georgia as to reduce markedly both acreage and production. In 1933 this disease appeared for the first time west of the Appalachians and caused serious losses in eastern Tennessee. In the Northeastern States a bacterial wilt of sweet corn has proved increasingly serious during the last 3 years. In 1932 it caused greater losses in this region than at any time since its discovery on Long Island 35 years ago and materially reduced the supply of early sweet corn available over important marketing areas in New York, New Jersey, Pennsylvania, and the States west of this group. So severe was it in Connecticut in 1933 that in the "emergency gardens" tilled by the unemployed the sweet corn was a total failure.

Such losses are of great, sometimes tragic, importance to the individual. From the standpoint of the agricultural industry as a whole, however, and from the standpoint of effective land utilization, losses from plant diseases are more important because of their fluctuation than because of their absolute size.

Disease Control Needed to Reduce Costs

Once the cause of a disease is thoroughly understood and a commercial control worked out and regularly practiced, it ceases to be so great a factor in crop fluctuation. This, then, is the end toward which the work of State and Federal students of plant diseases is now tending; not to control diseases in order that larger total crops may be produced, but to control them so completely that crops can be produced more

cheaply, and to understand their hazards so fully that the losses from plant diseases can be largely foretold in order that planting a crop may be to that degree less a "leap in the dark."

Future development should greatly increase the importance of plant-disease information to land utilization. When it is possible by careful surveys to determine those areas in which diseases are likely to be particularly troublesome, it will then be possible to prevent many disastrous experiments in growing new crops as well as ill-advised attempts at settlement.

NEIL E. STEVENS, *Bureau of Plant Industry.*

PLANT Shipments Freed From Diseases and Pests by New Methods

Sterilizing and disinfecting treatments are applied to plants and plant products under quarantine regulation in order that they may move from areas or countries where particular fungus or insect pests are known to be present to other regions without danger of spreading such pests. This eliminates the risk of pest dispersal and at the same time provides for the natural commercial movement of the commodity. The necessity for such treatments was early recognized in the administration of Federal plant quarantines and numerous methods of treatment for various pests have been authorized and applied to plant products. With the progress of research work on pest control, it is possible to modify these treatments and develop new processes which are more economical or more efficient or interfere less with the commercial movement of the regulated products.

An infestation of the Mediterranean fruit fly in Florida discovered in the spring of 1929 and found to be rather widespread over the citrus region of the State made necessary the application of some treatment to the 1929-30 crop if it were to move without danger of dispersing this pest. Tests by the Bureau of Entomology indicated that the larvae and eggs of the Mediterranean fruit fly could be destroyed within the fruit by heating it to a temperature of 110° F. and holding it at that temperature for 8 hours. It was also shown that such treatment could be applied to citrus fruit grown in Florida without injury. A treatment was then developed which consisted in heating the fruit contained in field boxes in a specially designed room by means of hot, moist air applied in large volume. By this method, the fruit could be heated uniformly throughout the room without danger of overheating. The treatment could be applied to 40,000 pounds of fruit in a single room in a period of 14 to 16 hours, allowing 6 to 8 hours to heat the fruit to 110°, and a holding period of 8 hours at that temperature. About 5,000 carloads of citrus fruit which were from within the regulated area but were not known to be infested by this insect were sterilized by this process, the fruit moving to its normal markets without danger of dispersing the pest.

This method of treatment was also applied with success to avocados in Florida. A similar method has since been developed by the Bureau of Entomology for the treatment of narcissus bulbs infested with bulb flies. The treatment might be applied to a number of other perishable commodities where the thermal death point of the pest is lower than the temperature at which the commodity will be injured.

Sterilization By Refrigeration

Refrigeration was also employed in the sterilization of citrus fruit to eliminate the possibility of disseminating the Mediterranean fruit fly. It was determined by the Bureau of Entomology that holding fruit at a temperature of 30°-31° F. for 15 days seemed to insure the death of eggs and larvae of this pest. As this temperature was only slightly lower than the cold-storage temperature at which the fruit will keep best for the longest period, it was found to be well adapted to this work. The treatment was applied commercially to some 500 carloads of citrus fruit from Florida at the end of the shipping season, thus combining sterilization with the storage of the fruit for later markets.

The method has since been applied to citrus fruit from the lower Rio Grande Valley of Texas following an infestation of Mexican fruit fly to insure freedom of the fruit from this insect. Two hundred and fourteen carloads were treated in this case. The treatment is applicable to many other types of fruit and vegetables, as well as nonliving plant products which are not injured by temperatures below that necessary to destroy the insect pest which may be infesting them. These two methods of treatment for fruit flies have been employed only as additional safeguards for the treatment of fruit exposed to infestation and were not used for treatment of fruit known to have been subject to fruit-fly attack.

Shipments of green beans from the area heavily infested with the Japanese beetle when the adult beetle is numerous are very liable to be infested with these insects and inasmuch as long-distance shipments are made they may carry the beetle well outside the infested area and result in establishing new infestations. A machine for freeing the beans from these insects was developed which consisted of two drums of wire mesh, one within the other, the inner drum being about 20 inches in diameter and 10 feet long, supported in an inclined position by a shaft through the axis and suitable braces. The drums are open at both ends, the beans are fed into the upper end through a suitable hopper, and as the drums are rotated they progress to the lower end, where they are caught in hampers. The beetles are shaken out of the beans and fall through the wire mesh to the ground. The machine is much more effective than hand-inspection and cheaper, costing only about 1 cent per bushel for operation, and having a capacity of about 1 bushel per minute.

Pressure Method for Killing Pink Bollworm

The elimination of the pink bollworm from cotton lint and linters is a problem of first importance in the prevention of spread of the pink bollworm. These commodities when produced in infested areas were formerly fumigated under vacuum with hydrocyanic acid at the cost of about \$1.50 per bale. It was found, however, that a pressure of 2,000 pounds per square inch in a mass of cotton would crush all seed contained therein sufficiently to kill any pink-bollworm larvae that might be present. It was determined also that such pressure was developed in a commercial compress and that cotton from the lightly infested area could be shipped after such treatment with little or no danger of transporting a live insect. This method was therefore authorized for all cotton except that grown in areas where the infestation was heaviest.

Further work showed that by passing the cotton in the form of a bat between heavy steel rollers held together by heavy springs just before it entered the press box and as part of the ginning operations, the same results could be accomplished. That is, sufficient pressure was applied to the cotton to crush any seed which might be therein and destroy any pink bollworm. This process had the advantage of being applied at little added cost, the operating cost being estimated at about 1 cent per bale. By this method, all the cotton was subjected to a uniformly high pressure, and the entire bale was free from possible infestation when it left the gin press. It was thus possible without decreasing the effectiveness of the treatment to substitute in certain areas a process which cost 1 cent per bale for application for one which had cost \$1.50 per bale.

A method of sterilizing cottonseed for planting, in which the seed, preheated by steam, was held for 1 hour at 145° F. in a steam-jacketed container, was developed. The apparatus was designed to operate continuously with a capacity of about 8 tons of seed per day. Careful tests showed that this treatment would sterilize seed without injuring the viability. This made possible the shipment of special varieties of cottonseed from the lightly infested area for planting, and made this seed available over a wider area, thereby benefiting the producer in that he received a higher price for his seed.

The object in this work is to make the treatments as simple and economical as possible, reduce interference with the commercial movement of the commodity to a minimum, and, at the same time, prevent the spread of the pest against which the regulations are directed.

LON A. HAWKINS, *Bureau of Plant Quarantine.*

PORK of Good Quality Grown Efficiently on Corn-Soybean Ration

Rapid expansion in the production of soybeans during the last decade has led to increased utilization of the crop in feeding livestock. Because of its high protein content, the soybean has become popular as a supplement to corn and other starchy feeds in the production of hogs. This often makes unnecessary the purchase of concentrated protein feeds. Soybeans contain about 36 percent of protein and vary in oil content from 12.7 to 20.5 percent depending upon the variety, the more common varieties used in hog feed averaging approximately 18 percent. Because of their high oil content, soybeans fed in large quantities produce soft or oily carcasses of unsatisfactory market quality. Another consideration in feeding soybeans is their deficiency in certain mineral elements; hence hog rations containing soybeans should include a good mineral mixture.

Rations of Corn and Soybeans

In cooperation with the Purdue (Ind.) University Agricultural Experiment Station, the Department has conducted a series of tests to determine the maximum proportion of soybeans that may be fed to hogs with corn without serious detriment to the quality of carcass. The plan of this series of experiments provided for a study of the effect of mixtures of ground corn and ground soybeans when fed to fattening hogs in the proportions 3:1, 6:1, 9:1, and 12:1, as compared with the effect, on a control lot, of a mixture of corn and tankage in the proportion of 12:1. The Purdue investigators also used another lot in which

one third part tankage was an added protein supplement to the 12:1 corn-soybean ration.

The Manchu variety of soybeans was fed in the Indiana experiments, whereas the Virginia variety was fed in the Department experiments, which were conducted at the United States Animal Husbandry Experiment Farm, Beltsville, Md. Three experiments were conducted at Purdue and two at Beltsville. All hogs were slaughtered and carcass observations made at Beltsville. The carcass-grading committee was composed of 3 members, 1 representing the Bureau of Animal Industry, United States Department of Agriculture; 1 representing the State agricultural experiment stations cooperating with the Bureau in soft-pork investigations; and 1 representing the Institute of American Meat Packers. In all the experiments the mixtures of ground corn and ground soybeans were self-fed, free choice, in dry lot, with mineral mixture. The mineral mixture was composed of 10 parts wood ashes, 10 parts 16-percent superphosphate, and 1 part common salt. The hogs also had access to pressed block salt. The principal results of these experiments are shown in summarized form in table 6.

TABLE 6.—*Summary of data from hogs fed various rations in dry lot*

Ration and proportion	Hogs fed	Period of feeding	Average weight		Average gain		Feed per 100 pounds gain	Average grading of carcass for firmness
			Initial	Final	Total	Daily		
Corn and soybeans:	<i>Number</i>	<i>Days</i>	<i>Pounds</i>	<i>Pounds</i>	<i>Pounds</i>	<i>Pounds</i>	<i>Pounds</i>	
3:1.....	38	77	115	222	107	1.39	468	Soft.
6:1.....	46	87	113	232	119	1.38	477	Medium soft.
9:1.....	47	83	113	231	118	1.42	444	Do.
12:1.....	37	87	118	236	118	1.36	501	Medium hard.
Corn, soybeans, and tankage:								
12:1:13.....	17	65	124	240	116	1.77	458	Do.
Corn and tankage:								
12:1.....	45	72	116	242	126	1.76	435	Hard.

In all cases the gain produced on the corn-soybean ration averaged over 100 pounds, with a variation in the finished weight of the hogs ranging from 205 to 243 pounds as the lot average.

Feed Consumption and Carcass Quality

From the standpoint of feed consumption per 100 pounds of gain the results were consistent at the two stations in favor of the 9:1 ration, when soybeans made up the sole protein supplement. The 12:1 ration was consistently the high-cost ration at both stations, an average of about 57 pounds more feed per 100 pounds of gain being consumed with this ration than with the 9:1 combination. The addition of one third part tankage to the 12:1 ration not only increased the rate of gain, but the pigs required on an average about 43 pounds less feed per 100 pounds of gain than with the straight 12:1 mixture. In no instance, however, did any of the feed combinations at either station equal in efficiency, so far as low feed consumption per 100 pounds of gain was concerned, the feed utilization of the control lots receiving corn and tankage in the proportion of 12:1.

The conclusion reached by the investigators in consultation with other specialists cooperating in the soft-pork investigations were as follows:⁹

⁹ Agricultural experiment stations of the following States have cooperated with the Department in soft-pork investigations and in the interpretation of results: Alabama, Arkansas, Georgia, Kentucky, Mississippi, North Carolina, Ohio, Oklahoma, Pennsylvania, Indiana (Purdue), South Carolina, Tennessee, Texas, and Virginia. The Institute of American Meat Packers has also cooperated.

Hogs with initial weights up to 130 pounds, when fed a corn-soybean ration in the ratio of 3:1, will not usually produce firm carcasses if slaughtered after a gain of approximately 100 pounds or more has been made on this ration. Only 8 percent were in the medium-hard class, the remainder being medium soft or soft.

Thirty-six percent of the carcasses of hogs fed the 6:1 corn-soybean ration were firm (hard or medium hard). However, heavier hogs having initial weights of 115 pounds or more and gaining at least 1.5 pounds per day when fed for a period of 10 weeks or longer usually produce firm carcasses.

Approximately 50 percent of the carcasses of the hogs fed the 9:1 corn-soybean ration were firm, whereas 65 percent of the carcasses of those fed the 12:1 ration were firm. With these two rations also, the heavier, faster gaining pigs normally produced firm carcasses. When one third part tankage was added to the 12:1 ration, 88 percent of the carcasses were firm, whereas 91 percent of the carcasses of the control group fed the 12:1 corn and tankage rations were firm.

From these results it appears that initial weight, ration, and rate of gain are important factors that influence firmness in the carcass. In general, hogs well grown on nonsoftening feeds to a weight of approximately 115 pounds or more and making subsequent gains of approximately 100 pounds on a corn-soybean ration with gains of 1.5 pounds or more daily, produce firm carcasses when the proportion of soybeans in the ration is not greater than 1 part of soybeans to 6 parts of corn. Of the corn-soybean rations, the 9:1 combination produced the most economical gain.

J. H. ZELLER, and O. G. HANKINS,
Bureau of Animal Industry.

POTATO Losses in Handling Reduced by Simple Equipment

In the Aroostook area of Maine, the bulk of the potatoes grown must be stored either on the farm or at the trackside, because the existing transportation facilities cannot handle more than a tenth of the crop during the harvest season. Current harvesting and handling methods in that area cause injuries to potatoes averaging about as shown in table 7. The minor bruises prior to storage, affecting about 40 percent of the potatoes harvested, result in grade injuries in storage amounting to 3 percent of the crop stored. Respiration of the potatoes in storage causes a loss of about 5 percent.

TABLE 7.—*Injuries to potatoes caused by harvesting and handling methods, in Aroostook County, Maine*¹

Operation	Grade injury	Minor injury	Total injury
	Percent	Percent	Percent
Digging.....	2.15	16.16	18.31
Picking into baskets.....	.36	1.86	2.22
Emptying into barrels.....	1.94	6.22	8.16
Placing in storage.....	2.65	16.47	19.12
Moving to grader.....	1.14	12.13	13.27
Grading.....	1.75	18.48	20.23
Bagging or barreling.....	4.41	6.65	10.06
Total.....	14.40	76.97	91.37

¹ Prepared by William E. Schrumpf, Maine Agricultural Experiment Station.

The grade injuries that occur up to the time the potatoes pass over the picking table, including the increase in injuries caused by storing potatoes with minor injuries, amount to about 13 percent of the total. These should all be removed as the potatoes pass over the table, but the potatoes injured as they drop into bag or barrel will show up only in the market or the kitchen, and while they may not cause an immediate loss to the shipper, they will cause a prejudice against the brand of potatoes he ships, and are thus more serious than the injuries that occur before weighing and selling.

Mechanical Digging Reduces Damage

Mechanical diggers cause fewer injuries than digging by hand. Digger injuries can be reduced by running the continuous-elevator type of digger low at the rear end, and by padding the tines and projections of the shaker-elevator type of digger. Plenty of dirt carried up over the elevator will reduce bruises with either type. The practice of digging every other row of potatoes allows the pickers time to pick up before the digger makes the second trip over, thus saving the potatoes which roll down between the rows and would be in the path of the horses and the digger wheels.

Picking potatoes into baskets of the split-wood variety causes less injury than picking them into metal baskets. The data in table 7 are for potatoes picked into split-wood baskets.

In the Aroostook area practically all of the potatoes are hauled from the field in 11- and 12-peck stave or veneer barrels, and about 2 percent of them are injured in grade when dumped into the barrels. Many farmers have reduced this injury by padding the rims and bottoms with burlap. Barrels are also used in taking potatoes from basement bins, farm storage, and sometimes bins on the same floor, to the grader; and from the grader to the car when potatoes are being shipped in bulk. Since relatively few barrels are used for these purposes it would be profitable to pad the rims, lower sides, and bottoms with sponge rubber.

About half of the potatoes stored in the Aroostook area are dumped from barrels from a "rolling plank", and the other half from barrels through scuttle holes. Much injury is caused by allowing the rolling plank to rest directly upon the potatoes, but the rolling plank may be supported by cross members resting on cleats nailed to the bin wall without injury to the potatoes. After the bins are half full, the rolling planks are removed, and the potatoes are elevated to the floor above the bin and dumped through scuttles. The pile is first built up to the mid point of the ceiling by dumping through a twisted sack chute supported at the scuttle by being nailed to a wood frame or by being sewed to an old tire casing. After the pile is built to the level of the scuttle the sack chute is removed and the potatoes are then dumped through the padded scuttles. Padding around the scuttles helps to prevent bruises.

Rope-Bottomed Hopper

An objection to dumping through scuttles, in addition to the bruising of tubers, is that a pyramid or a wedge of very dirty potatoes is built up under the scuttle holes. Ventilation of this dense mass is difficult, and a good deal of sprouting and rotting results. To correct this condition a large percentage of farm-stored potatoes are run over a slatted

wooden rack or hopper before being dropped through the scuttle. In this way often 5 percent of the harvest is removed in the form of dirt, rocks, and small potatoes; but such racks increase the grade injuries by

FIGURE 79.—Rope-bottom hopper for freeing potatoes of loose dirt before storage.

about 1 percent. To obtain the advantages of the cleaning hopper without its disadvantages, a rope-bottomed hopper was built (fig. 79) consisting of a 2-by 4-inch frame over which $\frac{3}{8}$ -inch rope is stretched three quarters of an inch apart on centers. At the ends of the hopper the rope is bent around $\frac{3}{8}$ - by 2-inch iron pins driven $1\frac{1}{2}$ inches into drill holes in the edges of the cross members.

The rope is continuous, and slack is taken up at the ends. This hopper was used in connection with a trough-bottomed conveyor (fig. 80) to handle 3,000 barrels of potatoes in the fall of 1933, and

FIGURE 80.—Trough-bottom elevator, without cleats on belt, piling potatoes in storage bin.

over 100 barrels of dirt, rocks, and small potatoes were removed. Very little bruising occurred when this equipment was used.

Cleated canvas conveyors for piling potatoes are on the market, but they are not popular because they are heavy and hard to move around,

and bruising is increased by the cleats as they pass through a filled hopper. The conveyor shown in figure 81 was designed to overcome the disadvantages of the cleated conveyor and of the usual hand methods of dumping through scuttles and from planks. This conveyor worked very satisfactorily in storing the 3,000 barrels mentioned above. It is 18 feet long, and delivered 8 feet higher than the receiving end when a continuous stream of potatoes was fed from the rope hopper. By raising the lower end 2 feet above the floor, potatoes were stored to a depth of 10 feet. A $\frac{1}{2}$ -horsepower electric motor, washing machine reduction unit, and 16-inch canvas conveyor belt were used.

The conveyor shown in figure 81 was designed for taking potatoes from the bin and elevating them on to the first grading belt of a grader. It consists of two flights and one continuous conveyor belt. The lower flight is horizontal and fits into a 16-inch by 8-inch conveyor trench that runs the length of the bin; the upper flight elevates the potatoes

FIGURE 81.—Conveyor elevator for unloading potatoes from storage bin to grader. (Only one end of horizontal flight is shown, at right.)

on to the belt of the grader. The conveyor trench, like those used in corncribs, has a cover of slats which are removed one at a time as the potatoes cease to run down. The same motor, drive, and belt were used as for the elevator described above. This conveyor was used with a small lot of potatoes in the spring of 1933, and handled them with less bruising than usually occurs with potato forks. Bruising caused by the type of potato fork shown in figure 81 can be reduced by placing old sprayer hose over the back one third of the tines.

Reducing Injury by Graders

Graders cause but little more injury than the usual operation of moving potatoes to the grader hopper, but the average grade injury of about 2 percent may be reduced by padding ramps between runs of conveyor belt and grading chain, and such corners as the moving potatoes might hit. Keeping the grader in adjustment and repair is equally important in preventing grader injury. The greatest injury in grading potatoes occurs in dropping from the grader into the barrels or sacks. The re-

sulting grade injury is about 4 percent, and these injured potatoes are not picked out but go to market, as already noted. Barrels may be padded. When the potatoes are shipped in sacks the most common method of preventing injury is to pad the floor heavily under the bag holder. Another common method is to tie up the bottom until the sack is partly filled, to decrease the drop of the first potatoes. Investigators are experimenting with tilting supports for sacks and barrels to reduce the injury from this source.

In all steps in the handling, it has been found, the temperature of the potatoes affects the amount of injury suffered. If the potatoes have a temperature of 50° F. or above, appreciable less bruising results than when they are handled at lower temperatures. In a storage house one bin may be warmed without affecting the others, by blowing warm air from the main alley into the conveyor trench of the bin to be warmed. This is not the least important means, from the standpoint of either effectiveness or economy, that is suggested for reducing the losses commonly suffered in storing and handling this crop.

A. D. EDGAR, *Bureau of Agricultural Engineering.*

POUSTRY Meat Production Costs Reduced by Cross- Breeding and Good Diets

The production of poultry meat and the control of its quality may well begin with breeding for rapid rate of growth and good quality of carcass. The more rapidly a chicken grows the less it costs to raise it. Not only is less feed eaten per pound of gain, but the bird can be marketed at an earlier age. It is also true that the meat of the faster growing chicks is usually of better quality. Once suitable chicks have been obtained, the chief problems are those of management and feeding.

Breeding for Rapid Growth and Quality

Only within recent years has much thought been given to the possibility of utilizing breeding principles in producing rapid growth and high market quality in chickens. One means of doing this is to cross-breed. Several crosses have been tried which seem to have a beneficial effect on rapidity of growth and quality of meat at least up to 10 or 12 weeks of age, although the results have not been adequately verified. These crosses are as follows: Rhode Island Red and White Wyandotte; Rhode Island Red and Light Sussex; Rhode Island Red and Barred Plymouth Rock; and Dark Cornish and Barred Plymouth Rock.

Crosses of the White Leghorn with some of the heavy breeds have produced results that were not so desirable. They are: White Leghorn and Barred Plymouth Rock; White Leghorn and Rhode Island Red; White Leghorn and White Wyandotte; and White Leghorn and Jersey Black Giant.

It is noteworthy that the sex of the chicks resulting from all the crosses of the first group may be ascertained at hatching time by the color of their down. However, practically all the crosses of the second group have no definite indications of the differences between sexes of the day-old chicks.

In the crossbreeding studies carried on at the United States Animal Husbandry Experiment Farm, Beltsville, Md., the cockerels from

crosses of Single-Comb Rhode Island Red males with White Wyandotte and with Light Sussex females showed a rate of growth and quality of meat superior to those of the other crossbred stock, as judged from the finished carcasses at 12 weeks of age. The females were held for other experimental work.

Of the purebred cockerels at 12 weeks of age, the Rhode Island Reds were the heaviest and had the best carcasses; the Light Sussex were next in weight, and the White Wyandottes weighed the least, the last two breeds averaging about the same in quality. The Rhode Island Red males were approximately 16 percent heavier on an average than the White Wyandottes, and the carcasses 8 percent higher in quality. In the crosses of the Rhode Island Red with both the Light Sussex and the White Wyandotte the progeny were heavier and, on an average, about 20 percent better in quality than the best of the pure breeds. This work is being continued in order to verify the results.

It is believed that in the standard breeds used in making these crosses continued selection and breeding will aid materially in producing individuals much superior in rapidity of growth and quality of meat.

Management and Quality of Diet Important

When feeding is contemplated with the idea of reducing the costs of production, it is likely to be unsuccessful unless considerable attention is given to the quality of the diet and to management, particularly sanitation. Cheap diets do not lead to lowered costs of production if they are of poor quality. Management is a problem which each individual must work out to suit his own conditions.

When young chicks are raised on good range, such as bluegrass or alfalfa, they do not require so much of the more expensive protein supplements as when raised on a poor range, bare lot, or in confinement. The ideal range is one that is well drained, either naturally or artificially, and has a good stand of bluegrass or one of the legumes such as alfalfa.

When plenty of skim milk or buttermilk is available, young stock on good range will make economical gains and produce a good quality of carcass on a low-cost diet made up of ground corn and all the milk they can drink. If it is necessary to purchase milk in some processed form, it can seldom be fed freely without considerably increasing the cost of the diet. In this case a suggested economical mash consists of 90 pounds of ground corn, 5 pounds of dried milk, and 5 pounds of a good-quality meat product. Economical gains and good growth have been obtained, at Beltsville, on a diet of corn meal and buttermilk when the chickens were raised in good-sized yards containing growing green feed.

When the quality of the range is poor it is best to use a mash mixture of 68 pounds of corn, 10 of wheat bran, 10 of wheat middlings, 5 of dried milk, 5 of good-quality meat product, and 2 of ground oyster shell or high-grade limestone. In any case, the chicks should receive 1 pint of cod-liver oil with each 100 pounds of mash for the short periods that they are confined in the brooder house before being allowed access to free range and direct sunlight. The simple diets should be used only when supplemented with range.

Using range to supplement the diet is highly advantageous and reduces cost of production. If it is necessary to raise the young stock in confinement, the generous use of high-quality protein concentrates is economical. Considerable attention must be given to all the ingre-

dients used in a complex diet, or severe losses may result from heavy mortality, poor growth, and nutritional perosis (leg weakness).

A complex diet that has given good results, at Beltsville, when fed to chicks raised in confinement is composed of 40 pounds of ground corn, 15 of ground wheat, 10 of good-quality meat product, 10 of oatmeal, 6 of rice bran, 5 of dried milk, either skim milk or buttermilk, 5 of fish meal, 5 of alfalfa-leaf meal, 3 of ground oyster shell or high-quality limestone, and 1 of salt, plus 2 pounds of cod-liver oil. If rice bran is not available it may be replaced by 15 pounds of ground oats.

Three Classes of Marketable Chickens

When chickens have reached the market stage they can usually be divided into three classes. The first class is made up of those individuals that are of good weight and have well-filled-out bodies. Such birds are already in good finish and should be marketed without attempting to improve them by fattening. The second class comprises those individuals that have well-developed frames carrying relatively little meat. These birds will make fair gains, and the fattening process will change the quality of their carcasses from the lower to the higher grades. The third class is made up of the remaining birds. Most birds in this class, if wormed, will respond remarkably well with extra gains and improvement in quality when fattened.

With a little experience it is relatively easy to decide just how long a group of birds should be kept on the fattening diet. In general, the younger the birds the longer they can be fattened profitably, but it is not economical to keep fattening birds in batteries and on feed longer than 2 weeks.

Complex feed mixtures are not necessary for the finishing of market poultry, especially when plenty of milk is available at low cost. When milk costs are high, reasonably good results can be obtained by using somewhat more complex mixtures containing soybean meal and some meat product in place of milk.

Two of the most commonly used diets for fattening are ground oats mixed with milk, and equal parts of ground oats and ground corn mixed with milk. The former mixture produces good gains and excellent "bloom" of carcass. The latter usually gives as good gains as the former and is somewhat cheaper. Both of these fattening diets have been used with good results in fattening tests carried on at the Department's farm at Beltsville. A mixture, with water, of equal parts of soybean meal and a good-quality meat product may be used with fair results to replace milk in a fattening diet.

Improper killing and dressing of a prime market bird will cause it to be placed in a much lower grade. Therefore, in order to obtain extra-fine quality table poultry, dry picking seems to be essential, though very good results may be obtained also by the proper use of the semi-scald method.

It is evident that there is a possibility of increasing profits in raising chickens not only by a greater rate of growth and reduction in costs, but also by increasing the market value through better quality of the carcass. One of the best means of accomplishing these results is the use of proper breed crosses. Rapid growth and a high quality of meat depend also on careful coordination of feeding and management.

C. W. KNOX and H. W. TITUS,
Bureau of Animal Industry.

PREDATOR-TRAP Device Safeguards Species That Are Harmless

tended. The force of trappers engaged in predatory-animal control work under the supervision of the Bureau of Biological Survey are under strict instructions to avoid the trapping of such fur bearers as minks, martens, foxes, and weasels and other animals unless locally detrimental to livestock, game, and poultry production. Birds, rabbits, and prairie dogs, ground squirrels, woodchucks, and other rodents may spring traps set in ideal sites for coyotes and wolves. This not only results in unnecessary destruction of innocent wild life but prevents capture of the larger predatory animals. It also tends to arouse their suspicion, thus making them trap shy, and ruins the chance of capturing an animal that perhaps has destroyed thousands of dollars' worth of livestock during its marauding career. Hunters will lose much valuable time, and their efficiency will be greatly decreased in areas where such trap interference is common, unless the traps can be so adjusted as not to be sprung by valuable or harmless small mammals or birds. Many devices have been developed to safeguard the smaller creatures and to prevent their interfering with the traps.

In setting traps for predatory animals trappers frequently capture individuals of species other than those for which the sets were in-

FIGURE 82.—Devices to prevent capturing small mammals and birds in traps set for predatory animals: A, Pan supported by twig (grass or a light coil spring may be used); B, splint support; C, forked-twig support; D, Biological Survey pan spring.

Simple Field Devices

A common method is to insert a piece of stiff grass, such as the saccaton grass of the Southwest, or a pliable green twig, in a vertical position between the trap base and the bottom of the pan (fig. 82, A). The twig should be a little longer than the distance between the base and the pan, so that it will be slightly curved when sprung into place. Another satisfactory method utilizes a piece of spring steel, such as may be obtained from an old phonograph or a clock, cut in lengths sufficient to exert the desired tension when placed between trap base and pan.

A splint cut from a piece of dry cedar, redwood, or other brittle wood will aid in making traps selective for predatory animals. The splint should be approximately the length of the jaw of the trap and one sixteenth to one eighth inch thick. It should be cut with a slight depression in the middle, wide enough to carry the trap pan when set (fig. 82, *B*). The ends of the splint rest on the straight top surfaces of the outer or loose jaw, about one half inch from each jaw post, and the trap pan rests on top of the splint. The dry brittle twig will break under the weight of a coyote, but will remain firm when lighter animals or birds step on it.

A V- or Y-shaped tension device (fig. 82, *C*) cut from the crotch of a willow, cherry, or other pliable twig, is successfully used by many trappers. One end of the main twig is placed across the trap base, and the other extends back parallel with the cross arm. The lateral twig is placed beneath the pan and provides a springlike tension. The tension may be varied by using twigs that differ in size and strength.

Biological Survey Pan Spring

One satisfactory method of providing selectivity in trap sets has recently been developed by the writer in cooperation with the personnel of a trap-manufacturing company. This contrivance (fig. 82, *D*) may be attached to any standard no. 3, 3½, 4, 14, 44, or 114 Newhouse trap. It is provided with a slot that fits under the beveled edges of the pan post. The spring rests on top of the cross arm and engages the underside of the trap pan. When pushed back so that the apex of the slot sits snugly against the front of the pan post, the spring carries a tension of 3 to 5 pounds on a set no. 4 trap. When pulled out so that the fingers of the spring are barely engaged under the beveled edges of the pan post, the tension is increased so that it takes a 5- to 8-pound weight to spring the trap. With this variable tension, it is possible so to adjust the spring that the trap may be set to meet conditions in different localities. It is well to set the spring with a maximum tension where porcupines and badgers are abundant, but with less tension where ground squirrels, rabbits, and other small animals are causing interference with traps set for predators. In using these springs it is to be borne in mind that the tension increases as the spring is pulled outward.

Several thousand of these springs have been supplied to trappers working for and under the supervision of the Biological Survey, and have proved a practical means of providing the selectivity so long desired in trap sets. It is known as the Biological Survey pan spring and is now on the market. A patent on it has recently been granted, dedicated to the free use of the public.

In using any contrivance to provide tension on the pan spring it becomes necessary for the hunter to make adjustments in the trap so that the pan maintains the proper position. If it is too high, a sharp blow with a hammer on the outer side of the upturned end of the cross arm will force the trigger inward, thus lowering the position of the pan. If the pan is too low the upturned end of the cross arm may be bent outward or the trigger may be bent slightly upward with a pair of pliers. Each trap should be carefully adjusted to prevent the pan spring or other tension arrangement from interfering with proper setting or speedy action.

ALBERT M. DAY, *Bureau of Biological Survey.*

PRUNING Young Forest Trees Provides Work and Gives Profitable Crops

In many parts of the United States lands not under cultivation are naturally restocking to forest trees. Many farmers and landowners find themselves in the timber-growing business, simply by allowing trees to grow on lands otherwise idle. The business of establishing forest plantations also is gaining headway.

The grade of lumber cut from second-growth stands is for the most part seriously lowered by the many knots which mark the growth of branches from the tree. Early removal of the lateral branches, whether in natural stands or plantations, will greatly increase the intrinsic value of the lumber cut from the trees later (fig. 83).

Nature pruning, accomplished by close spacing of the trees, is often only partly effective. Even in plantations spaced 6 by 6 feet, branches which die from shading often remain on the trees for a long time, or

FIGURE 83.—Norway pine plantation 23 years old: A, Before pruning; B, after pruning. The larger trees in this plantation should have been pruned at least 5 years earlier. Pruning saw mounted on long handle shown leaning against tree.

the dead branches break off at some distance from the trunk, leaving projecting stubs which cause loose and defective knots, and prevent the production of clear lumber.

Artificial pruning is a means of supplementing the natural process, or it may be the sole reliance in very open stands. The pruning of forest trees is an established practice in Europe. In the United States the present surplus of labor would seem to afford an exceptionally good opportunity to begin a more general practice of forest pruning.

In an analysis of lumber cut from $4\frac{1}{2}$ acres in a 42-year-old stand of loblolly pine in Louisiana in 1930, it was estimated that, had the trees been pruned of lateral branches for a height of 16 feet when they were 4 to 5 inches in diameter at breast height, the value of the lumber would have been increased about \$100 per acre over the value of that actually cut. If this had been done, the percentage of lumber classed

in the best grades would have been increased from $2\frac{1}{2}$ percent to 42 percent. The increased value discounted at 6 percent compound interest would have allowed an expenditure of \$17 per acre 30 years earlier to conduct the pruning.

Preliminary experiments indicate that pruning costs should run well below \$17 per acre. Time records on Norway pine trees in a plantation 23 years old in Wisconsin show that a total of only about 10 minutes per tree is required to prune the lateral branches to a height of 16 feet. In any stand not all of the trees need to be pruned. Usually the pruning would be confined to trees that are to grow to the end of the rotation.

Pruning tools are simple. The branches below a height of 6 or 7 feet can be quickly cut with a straight pruning saw having rather coarse

FIGURE 84.—Examples of efficient and inefficient methods of pruning branches. A, Norway pine immediately after pruning, with branches cut close to the stem of the tree; B, white pine pruned 2 years. Projecting branch stubs will cause knots for years to come.

teeth. For branches from 7 to 12 feet above the ground a pruning saw with a slightly curved blade and with teeth on each edge should be mounted lengthwise on a straight handle about $6\frac{1}{2}$ feet long. The back of the blade may be used to make a small cut on the underside of the branch if there is a tendency for the branches to strip down. For the higher branches between 12 and 16 feet, a handle about 11 feet long will be required.

For success in pruning it is important that the work be done when the trees are of proper size. As a rule, the branches should not be pruned from the upper one third of the trunk. Thus trees to be pruned to a height of 16 feet should be not less than 24 feet in height. However, pruning should not be delayed after the trunks are more than 3 or 4 inches in diameter. If the stands are rather open and the trunks taper considerably, the pruning should be done in two installments,

the first pruning reaching to a height of 9 or 10 feet when the trees are 15 to 18 feet in height, and the second to a height of 16 feet, following as soon as the trees have attained sufficient height. According to this program the size of the branches to be cut off ordinarily would not exceed a diameter of 1½ inches.

In all cases the branch cuts should be close to and parallel to the tree trunk, so that they will be covered quickly and smoothly by the increasing diameter growth of the tree (fig. 84).

In the South, where injurious insects are likely to multiply rapidly if green branches are left lying about the trees in summer, it is best to prune only during the autumn and winter seasons, but except in such cases the pruning may be done whenever opportunity offers. Pruning the young forest may be considered primarily as a slack-time or between-season job for men who would otherwise be idle. It thus serves the double purpose of providing profitable employment and producing a profitable timber crop so far in advance of that provided by "natural" or scrub second growth that there is no comparison.

B. H. PAUL, *Forest Service.*

PURCHASE of Lands for National Forests in East Extended in Summer of 1933

Allotment of funds under the President's Emergency Conservation program has helped greatly to speed up the land-purchase

program for national forests in the East which began 22 years ago under the Weeks law. This law, passed in 1911, provided for the purchase of forest land for the protection of the headwaters of navigable streams. In 1924, by the terms of the Clarke-McNary law, the authority was broadened to include purchases of land for timber production as well as for stream-flow protection.

While the provisions of these two acts were not limited to any particular part of the United States, they have been applied only to those parts east of the Great Plains. Only 26 percent of the total commercial forest area lies west of the Great Plains, but that region contains 95 percent of the existing national-forest area. And while 74 percent of the total acreage of commercial forest is in the eastern half of the United States, it has only 5 percent of the area of national forests. Under such conditions, the need for the enlargement of national forests in the East is urgent, and therefore all appropriations for purchase of forest land have been expended here. The general-exchange act and related acts will be depended upon for the consolidation of the Government-owned lands in the national forests in the West.

For a long time the maximum Federal program contemplated for the eastern half of the United States an ultimate national-forest area of 16,000,000 acres. It has, however, become apparent that eventually something more than 100,000,000 acres of forest land in the East should be protected and administered by the Federal Government in order to serve the public interest adequately. The eastern half of the country contains 90 percent of the population and the majority of the watersheds most important for navigation, water supply, and flood control.

Great and urgent as the need has been for the extension of the eastern forests, however, the realization of the control of even

16,000,000 acres has been delayed because of lack of funds, and by the first of the fiscal year 1933 prospects for speeding up the program were not very good.

At the close of the fiscal year 1932 there were a total of 42 purchase units, situated in 20 States east of the Great Plains within which purchases of land for national forest purposes had been sanctioned by the National Forest Reservation Commission, which passes upon all purchases. In 31 of these units, situated in 19 States, there had been purchased or was in process of purchase an aggregate of 4,727,680 acres of land. The total expenditure for this land had been \$21,203,021.93.

Virginia led all the States in the amount of land actually acquired, a little more than 600,000 acres. New Hampshire came next, with almost 500,000 acres, and North Carolina was third, with approximately 400,000 acres. In each of the States of Tennessee, Pennsylvania, and Wisconsin, more than 350,000 acres had been acquired, and in each of the States of Georgia, West Virginia, Arkansas, and Michigan, more than 300,000 acres.

By 1933 the economic situation resulted in a strong tendency to get rid of forest lands for what they would bring. In some cases money was urgently needed to relieve hard living conditions; in many others land was tax-delinquent or was becoming so. Since the appropriation during the fiscal year was barely enough to complete the purchase of lands previously approved, however, action on new offers seemed to be out of the question. This was despite the fact that recent developments in several Eastern States showed increasing interest in and approval of the work. Several States raised the limitations which had been placed on Federal purchases of land, and other States authorized purchases, or advocated them urgently.

\$20,000,000 Allocated by Executive Order

At this most opportune time, the President, by his Executive order of May 20, 1933, allocated for the purchase of lands \$20,000,000 of the funds made available by the act of March 31, 1933, thereby permitting early action upon the large acreage which had been offered, examined, and appraised, and covered by option prices acceptable to the United States.

This action has made possible the acceleration and broadening of the acquisition program. During the next 3 months there was approved for purchase by the Secretary of Agriculture and the National Forest Reservation Commission an area equivalent to about one fifth of the entire acreage acquired during the preceding 22 years, and almost twice as much as during the preceding fiscal year. The total is 941,625 acres, to cost \$1,763,964. Besides this, an extensive series of new purchase units and additions to existing units have been approved that will increase the area to be purchased to approximately 12,000,000 acres. Of the approved new units, 4 are in Mississippi, 4 in Missouri, 2 in Illinois, 1 in West Virginia, 1 in Michigan, 1 in Minnesota, 1 in Florida, and 1 in Puerto Rico.

The incomplete condition of purchase units had interfered with the best use of the Civilian Conservation Corps on eastern national forests. The new fund made available by the President greatly facilitated the allocation of these men to useful work.

Great impetus has been given to the establishment of adequate national forests east of the Great Plains. At the same time many needed improvements are being made and much constructive work, which otherwise would have been greatly delayed, is being accomplished by the men of the Civilian Conservation Corps on national-forest land.

BERYL G. GARDNER, *Forest Service.*

RABBIT-RAISING Profits
Materially Influenced
by Age at Marketing

Raising domestic rabbits for food and fur is today an important minor farm industry in the United States, though less than 20 years have elapsed since the Belgian hare craze was running rampant. Through the cooperation of the Bureau of Biological Survey, rabbit breeders' associations, the Federal Trade Commission, and other agencies, unscrupulous operations have now been curbed, and rabbit raising is on a sounder business basis than ever before. During the past 2 years, however, extremely low market prices and the competition of other meats on a decidedly below-cost-of-production basis have all but ruined many commercial rabbit raisers. As a result, the breeders are looking more and more for dependable basic facts on costs of production, and the Biological Survey is obtaining such facts by conducting experiments at the United States Rabbit Experiment Station, Fontana, Calif.

Marketing at 8 Weeks of Age

Among the Bureau's recent accomplishments in this work, one of the most important is its experimental determination that 5.3 pounds of feed, two thirds of which is alfalfa hay, will produce 1 pound of live rabbit at 60 days of age, including feed for the doe. On the basis of average prices that grain producers received for concentrates and alfalfa hay during the 9 years previous to 1933, the feed cost of producing 1 pound of live rabbit to this age is $5\frac{1}{4}$ cents, and buying grain from a dealer wholesale or retail would make the feed cost proportionately higher. In this experiment 90 New Zealand does bred for 4 litters a year produced per doe about 63 pounds of live 60-day-old rabbits—or more than 18 young weighing approximately 3.4 pounds each. However, certain individual does are consistently better producers, and there are rabbit breeders who have raised the productiveness of their rabbitry to a higher level, through careful management and selection, and by preventing losses due to unsanitary conditions and disease. Constantly increasing competition will make such management a necessity.

This experiment resulted in information especially valuable to rabbit breeders in sections where rabbits are sold at 2 months of age. In other sections the market demands are for heavier rabbits and for meat firmer and more tasty than that from rabbits just weaned.

Marketing Heavier and Older Animals

In order to determine the feed requirements of carrying young rabbits beyond weaning age, an extensive experiment was carefully conducted at the Rabbit Experiment Station in which the rabbits were fed until each individual had attained a weight of 6 pounds. Data on 263

animals, bucks and does in about equal number, show that, according to averages, young weighing slightly more than 3 pounds when a few days older than 8 weeks required a little more than another 8 weeks to attain a weight of 6 pounds, the does attaining this weight 4 days earlier than the bucks. The animals were given 8 different rations, but the average feed requirement for producing 1 pound of live weight was 2.51 pounds of concentrates, 3.77 pounds of alfalfa hay, and 0.55 pound of green feed. On the basis of the average prices that grain producers received for feeds during the 9 years preceding 1933 the cost of this feed per pound of increased weight in young rabbits would vary on the average from 6.4 cents to 7.9 cents, depending upon the kind of feed supplied. For all the rations used it would average 7.13 cents. Again it should be noted that buying grain wholesale or retail will increase the feed cost.

The results of these experiments show that the feed cost of adding 1 pound to the weight of rabbits between the weaning age and an age at which they weigh 6 pounds is 22 to 50 percent greater than the feed cost of producing 1 pound of weaned young. The kinds of feed supplied the young rabbits, however, were not identical with those supplied the older ones, and costs other than feed (interest on investment, service of buck, labor, hutch space, etc.) would be materially greater during the period when the young are kept with the doe. (The proportion of feed costs to total costs of raising rabbits has not been determined for either the nursing period or that after weaning.) On the other hand, approximately 15 percent of the older animals, some of which might have been sold at weaning time, died before they attained a weight of 6 pounds.

Relative Values of Products

To obtain data on the meat and the fur produced by young rabbits, the investigators slaughtered each animal used in the second experiment as soon as it attained the 6-pound weight. They found that, on an average, the dressed carcass, including liver and heart, comprised 54.9 percent and the green skins 9.2 percent of the live weight. These skins are being used in studies to determine the effect of various factors on the primeness of domestic-rabbit pelts. The percentages of the total weight of the dressed carcasses of each cut averaged as follows: Hind legs, 35.4; saddle, or back, 24.4; front legs, 12; liver and heart, 7.8; and the rib portion, 20.4.

As the rib portion carries the smallest quantity of meat but constitutes one fifth of the carcass, the Biological Survey has suggested that it might be a good marketing policy to sell the ribs separately, at a decidedly lower price per pound, increasing slightly the price on the more edible portions so as to maintain the same average price for the entire carcass.

FRANK G. ASHBROOK and CHAS. E. KELLOGG,
Bureau of Biological Survey.

RANCIDITY in Foods Delayed by Excluding Certain Wave Lengths of Light Foods having an annual value in the United States of nearly 2 billion dollars are subject to spoilage by rancidity. The loss due to this form of spoilage often amounts to as much as 5 percent of the total value of the product. Among the foods apt to become

rancid and unfit for human consumption are edible oils and oil-bearing foods, such as butter, lard, potato chips, peanut butter, nuts, coffee, dried-milk products, corn meal, whole-wheat flour, certain breakfast foods, biscuits, and crackers.

The form of rancidity so familiar to both manufacturer and consumer, while the result of oxidation, is to a large extent activated by exposure to light between the time the food is manufactured and its ultimate consumption. Foods are more apt to develop rancidity during the summer months when sunlight is long and intense. When oil-bearing foods are protected from light, rancidity is prevented or delayed. Experiments conducted in the Bureau of Chemistry and Soils have demonstrated that when commodities subject to rancidity are inclosed in green or black containers, rancidity is appreciably delayed.

Various oil-bearing foods were used in these experiments. First it was found that exposure to ultra-violet light for a few hours or to direct sunlight for a somewhat longer period caused oil-containing products to become rancid. Samples of the same products were then wrapped with such colored wrappers as were commercially available and exposed to direct and diffused sunlight both outdoors and in the laboratory. In every case the products in green wrappers kept free from rancidity for a much longer period than did those in wrappers of other colors. Potato chips packaged in the usual commercial wrappers became rancid within a week, whereas the same product wrapped in green remained fresh and edible for at least 2 weeks. Cashew nuts kept in a clear glass bottle and exposed to direct sunlight became rancid in 4 days, whereas another sample of the same kind of nuts kept in a green bottle under the same light conditions remained fresh for more than 8 months. Similar results were obtained with corn meal, peanut butter, walnuts, and lard.

Particular Shades of Green Necessary

Not every shade of green will thus retard rancidity. It was found that the shade of green most effective for this purpose is penetrated only by light waves of 4,900 to 5,800 angstrom units. This shade approximates chlorophyll green or grass green. A wrapper or container may appear to be the proper shade of green and yet allow harmful light waves to pass through. Hence, it is advisable to examine spectroscopically all wrapper or container material intended for protecting oil-bearing foods in order to be sure of their protective qualities.

Why does green rather than any other color delay rancidity? Every wave length of light from the extreme violet to the far red in the visible spectrum, as well as the ultraviolet and infrared in the invisible spectrum, acts chemically upon substances that absorb it. This applies not only to foods and numerous other manufactured products but also to pure chemicals and certain pharmaceuticals. It has been found that oils and fats absorb wave lengths of light in the ultraviolet and blue ends of the spectrum and to a slighter extent those at the red end. It is probable that the absorption of these wave lengths of light causes vegetable and animal fats to become rancid. Consequently anything that excludes these light waves from oil-bearing commodities delays or prevents rancidity. Wrappers or containers of the proper shade of green filter out these harmful light waves and allow only the green light waves to pass through.

Besides delaying or preventing rancidity, it has been shown that green better than any other color preserves the aroma, freshness, color, and flavor of commodities such as certain fruit juices, sauerkraut juice, and coffee. The discovery of a way to prevent rancidity in foods should benefit the farmer through increased consumption and also through increased prices.

There is hardly an industry using agricultural products that cannot profit in some way by the use of green in the packaging of its goods. The corn-meal, rice, smoked-meat, baked-goods, butter, lard, fish, and salad-oil industries are only a few that could realize appreciable savings by the use of a proper light-excluding wrapper or container.

The discovery that a certain shade of green has the property of preventing or delaying the development of rancidity has opened up a new field of research of importance to the farmer, the manufacturer, and the consumer alike, not only in the food industry, but in connection with nonfood commodities such as certain pharmaceuticals and cosmetics.

MAYNE R. COE, *Bureau of Chemistry and Soils.*

RAT Baits Canned to Aid Cooperative Antirat Campaigns A safe and effective rat bait packed in sterile tin cans ready for immediate use in cooperative antirat campaigns is the latest development in the Bureau of Biological

Survey's efforts to reduce losses caused by rats. Rats cause the farmers of the United States a yearly loss of more than \$200,000,000.

One of the most persistent demands upon the Department of Agriculture has been for information on practical methods of rat control, and for more than 25 years the Biological Survey has had specialists working on the problem. This at first was purely investigational, and the results were made available to thousands of farmers in printed bulletins. Later more direct assistance was given on a restricted scale by farm demonstrations and by advice on control procedure, following surveys of areas heavily infested with rats.

Beginnings of Cooperative Rat Control

With the growing realization that control of the migratory rat is more a community than an individual problem, organizations have called upon the Bureau to furnish leadership in cooperative antirat campaigns. Rat control on a community basis was inaugurated in 1920, when a provision was inserted in the Agricultural Appropriation Act authorizing cooperation in destroying injurious rodents. Early work along this line culminated in the Virginia State-wide antirat campaign in 1923, during which approximately 110 tons of poisoned bait were distributed in a single week.

Although highly successful from the standpoint of destroying rats, the Bureau's earlier campaigns were not entirely satisfactory because the active ingredient then used in the bait, barium carbonate, was responsible for some destruction of dogs, cats, chickens, and other domestic stock. As a result the Bureau returned for a time chiefly to the purely educational aspects of rat control, but redoubled its efforts to devise a means of rat repression that would not harm domestic animals or endanger human life. These investigations have resulted in the development and use of red squill on a commercial scale.

Red squill has proved to be as effective in destroying rats as were barium carbonate and other more virulent poisons, and in addition it has the highly desirable feature of being relatively harmless to other animals. This is because its taste is obnoxious to most of them, and, furthermore, when eaten it usually acts as an emetic. Rats, however, are unable to vomit, and fortunately do not find red squill unpalatable; thus they readily succumb to its toxic action, whereas human beings and domestic stock evade it. Red squill thus closely approaches the unique distinction of being a poison specific for this one rodent species.

Red-Squill Baits Effective

With the advent of red squill into the field of rat control in 1928, there was opportunity for renewing the cooperative campaigns. The original plan was for the farmers of a community or of a whole county to furnish the bait ingredients to be mixed at central points by rodent-control specialists of the Bureau. The farmers would then carry the prepared bait back to their premises, and all, in accordance with directions, would expose it simultaneously. This procedure met with such success that the limited personnel of the Bureau was unable to meet all the demands made for cooperation, as baits containing freshly ground beef and fish could not be prepared much in advance of actual use.

On account of danger of quick spoilage of ready-mixed bait prepared on a large scale, the mixing and distribution raised a serious problem. The solution appeared to be to mix the baits before the campaign season and then so to preserve them as to permit adequate and simultaneous distribution, regardless of the size or number of cooperative campaigns requested. For this purpose a suitable canned bait was finally perfected after extensive experiments in cooperation with the food-preservation laboratory of the Massachusetts State College and the Pharmacology Section of the Food and Drug Administration of the United States Department of Agriculture.

Powdered red squill was mixed by machine with ground horse meat, ground silver hake or whiting fish, and a combination of cereals. These

FIGURE 85.—Each package of cooperative rat bait consists of three 8-ounce cans, one containing meal, the second fish, and the third cereal. The three kinds of bait are exposed in rotation, cafeteria style, giving the rats a choice of food, but in all cases a lethal quantity of red squill. The package contains sufficient for 100 or more baits—about the right quantity for the average farm.

three were separately canned and sterilized in steam retorts. The new, ready-to-use canned baits proved to be safe, effective, inexpensive, uniformly toxic, always fresh, and easily handled. It was decided to prepare the bait in quantity for campaign use exclusively and to label it Cooperative Rat Bait (fig. 85).

As Federal funds were not available for the purpose, a revolving fund, maintained by the Massachusetts State College, was established and used in financing the purchase of ingredients and preparation and distribution of the baits. At a small canning factory on the New England coast, leased during the fiscal years 1932 and 1933, approximately 400,000 cans of these rat baits were prepared and distributed.

Cooperative rat campaigns, through which the rat baits are exclusively distributed, are for the most part organized by county agricultural agents on a county-wide basis in accordance with Bureau of Biological Survey plans. Features of these plans include educational and publicity drives, through newspapers and radio, to arouse a popular interest in rat riddance, followed by circular letters or other means of direct contact with every resident, to explain the campaign details and to give them opportunity to get the canned bait at cost. Advance orders are obtained, and distribution of the bait is made through community leaders or committeemen on the campaign date. All bait is put out on the campaign day by the farmers, and a report on the results is made to the county leader a week later.

Results Greatly Benefit Farmers

In dealing with as crafty a creature as the rat, 100 percent control cannot be expected. That cooperative antirat campaigns are successful, however, is amply demonstrated by the fact that of 12,650 persons in the Northeastern States who answered questionnaire cards following a single application of the canned bait, more than 6,600 reported the destruction of every rat on their premises, and most of the others reported partial riddance.

To gain information on the extent of losses from rats on farms, each cooperator was asked to estimate his own losses. The yearly average of nearly 1,200 farmers in the Northeastern States was almost \$35. Assuming that this average applies to other sections as well (except in the Rocky Mountain States, where rats are relatively scarce), the total annual loss from rats on farms of the United States would be more than \$211,000,000.

To lessen this tremendous loss and to check the menace of the rat to human health, the Biological Survey is striving to improve the baits and to increase efficiency in organizing and directing the cooperative antirat campaigns, and looks forward with confidence to increasing success in future efforts at rat control.

JAMES SILVER, *Bureau of Biological Survey.*

RESTOCKING of Marshes With Hand-Reared Mallards Not Proved Practicable

Among the many remedies suggested to meet the crisis that in recent years has confronted North American waterfowl, is the proposal that lakes and marshes be restocked with hand-reared ducks. Some sportsmen and conservationists have even urged the

establishment of Federal "duck hatcheries", where large numbers of eggs would be placed in incubators, the ducks hatched from them, and when sufficiently grown, used for restocking. States, sportsmen's associations, and individuals have adopted this practice in stocking upland coverts with pheasants, Hungarian partridges, and quail. As a precedent for Federal participation, proponents of duck hatcheries point to the many Government-owned fish hatcheries operated to aid in maintaining an adequate supply of food and game fishes.

With this situation in mind, it becomes desirable to look into the matter and, if possible, to learn what success might be expected from restocking marshes with hand-reared ducks. Almost all species of North American ducks have been reared in captivity, either from captive parents or from eggs or young taken in the wild, but for most of these species breeding has been accomplished only a few times and the results have been far from satisfactory. Usually it is necessary to simulate natural conditions on so large a scale that the quantity production required for restocking purposes has been entirely impracticable. Those who propose the breeding of wild ducks under artificial conditions generally have in mind the mallard.

FIGURE 86.—A, A domestic hen fostering mallard ducklings, a common method of rearing these birds for restocking; B, hand-reared mallards with heavy, stocky bodies. They lack the nervous temperament desirable in sporting ducks.

Mallard Ducks

Mallards breed freely and persistently in captivity; in fact, wild-caught birds tame so rapidly that in a few weeks or months they become thoroughly domesticated. In spite of all precautions, however, captive-bred mallards unfortunately are prone to degenerate into the common barnyard or "puddle duck" type of bird (fig. 86). Thus far, the writer has not seen a hand-reared mallard that he would consider a good sporting bird. Nevertheless, fairly large numbers of mallards have been raised and liberated by public-spirited individuals, sportsmen's organizations, and State game farms, and more than 3,500 have been marked with Biological Survey bands.

From its banding operations with native wild-caught waterfowl which have been continuous since 1920 and have resulted in the marking of more than 125,000 ducks, an average of about 12 percent have been recovered the first season, with a cumulative recovery over a period of years of 20 to 25 percent. These percentages have been maintained very closely season after season, regardless of species or place of banding. At least 50 stations for the trapping and banding of waterfowl have been or still are in regular operation in the region from Alberta, Saskatchewan, Ontario, and Maine south to Texas, Louisiana, and Georgia, and from Massachusetts, Maryland, and South Carolina west to British Columbia, Oregon, and California. The extent of these banding activities warrants confidence in the dependability of the recovery percentages recorded.

Applying the 12 percent "expectancy" figures to the 3,500 liberated hand-reared mallards, one would expect that during the first year return records to the number of about 420 would be received, with a total expectancy of 700 to 875 (20 to 25 percent). Actually, however, only 52 of these birds were subsequently reported. The percentage of return (nearly 1½ percent) was lower than that for many species of nongame birds.

A representative case concerns two lots of mallards produced on a large game farm in eastern Pennsylvania, where 800 were banded and released in 1930, and 1,500 in 1931. From a similar total of 2,300 wild-trapped mallards, first-season recovery records to the number of at least 275 would be expected, and ultimately nearly 600 would be reported. The fact is, however, that only 29 of the hand-reared mallards have been recovered and reported, and 21 of these, or about 71 percent, were taken within a radius of 100 miles from the point of release. This indicates almost complete localization, though of the remaining 8, a few traveled up the Atlantic coast to Quebec and New Brunswick, and in the interior to Michigan, Minnesota, Iowa, and Kansas.

Another lot of 231 mallards reared and liberated at Southampton, N. Y., produced only 2 local-recovery records, as against the 25 or more that typically would have resulted from the same number of wild-caught ducks. A third lot of 519 mallards raised and liberated on a Connecticut State game farm, produced only 20 records instead of the expected 60 or more. A fourth lot of 506 from a California State game farm yielded just 1 recovery record, as against at least 60 that should have been reported from that number of wild mallards.

Black Ducks

The black duck, a close relative of the mallard, has a much more wary and nervous disposition, and for one reason or another it has been produced in numbers at only a few clubs and game farms. Nevertheless several lots of black ducks so raised have been marked with Biological Survey bands.

At Southampton, N. Y., 519 were banded and released, and 73 of these were subsequently recovered. All but 18 were taken in New York, most of them within a short distance of the banding point, but a few traveled north to Quebec and New Brunswick and south to Maryland. The total recoveries constitute more than 14 percent of those released, and while this is below the normal expectancy (20 percent), it more nearly comes up to the expected recovery than does the recovery of mallards.

The liberations at Southampton are of peculiar interest because of the fact that in 1927 and 1929, of 219 black ducks released, 32 produced return records, whereas of 231 mallards released in the same years, only 2 recovery records were obtained. The recovery percentage for the mallards has been about 0.9 percent, while for the black ducks it has been nearly 15 percent.

The only other comparable record available for the black duck concerns 77 hand-reared birds banded and released in 1928 at a Connecticut State game farm. Of these, 10 were subsequently reported, or practically 13 percent, which again is more nearly comparable to normal expectancy from banded wild-caught individuals. This is to be compared with less than 4 percent obtained from a liberation at the same point of nearly 7 times as many mallards. Also, the black ducks were much better distributed, only two being killed locally, the others being reported from points south to Maryland and Virginia.

An Unpromising Outlook

Though the available evidence is insufficient for general conclusions, it appears that under present methods, efforts to restock waterfowl marshes with hand-reared mallards are doomed to failure. Efforts with black ducks, however, are somewhat more successful. What becomes of the liberated hand-reared mallards is not known. Possibly, because of their semidomestication, they are merely leading lives of indolence in the marshes, refusing to migrate or to fly for the hunter; or else, untrained in the rigors of natural environments, and being solely on their own resources, they may be unable to cope with living conditions and so succumb rapidly to the elements and to natural enemies. If, however, the former hypothesis should be found correct, then the progeny of these birds may be an asset to our supply of game waterfowl. Need for a more thorough study of the problem is indicated, both in the field and on game farms.

FREDERICK C. LINCOLN,
Bureau of Biological Survey.

SEED Generally Will Not Stand Both High Moisture and Warmth

The preservation of seed from harvest to planting time is of primary importance to agriculture and all plant-production work. With many crops and under many conditions it is important to keep seed longer than from harvest to the next planting season. Aside from insect injury, the two conditions destructive to the life of seed are high moisture and high temperature. In general, seed will endure relatively high moisture if the temperature is low but not freezing, and relatively high temperature if the moisture content is kept low. A combination of high moisture content and high temperature induces rapid respiration and accompanying rapid destruction of the vitality of the seed.

When seed is produced in a moist climate it will retain a high percentage of moisture, and when kept on shipboard for a long time, as in the case with some imported seed, it loses vitality rapidly when brought into a warm climate. This has frequently happened with imported seed that was produced in the moist climate of northern Europe or that has been brought from the other side of the earth. Chewing's

fescue seed, with a high moisture content after 2 months on shipboard, has arrived practically dead, while other shipments that had a low moisture content when shipped have arrived in good condition. Much of the seed of hairy vetch grown in the humid areas of northern Europe arrives in the United States with a high moisture content and loses its vitality rapidly when taken to the warm climate of the South Atlantic seaboard and the Gulf coast.

In the handling of grain for feed and milling, low moisture content is recognized as one of the most essential elements of quality, and equipment for drying is recognized as essential in storage elevators. In connection with seed for planting, moisture content and drying equipment have been given little attention except to a limited extent in the case of corn on the northern edge of the Corn Belt, although seed begins to lose its vitality sooner than its feeding or milling qualities.

In general, seed should be dried carefully at harvest time and kept protected from moisture as far as possible. When seed produced in a cool climate is to be used in a warmer climate, it should not be moved until near seeding time. Even a seed as easily injured as onion may be kept in good condition for unusually long periods and in a warm climate if it is carefully dried and put in airtight containers, as is the case with Bermuda onion seed raised in the Canary Islands and so extensively used in Texas and the Southwest. Cold storage offers another means of keeping seeds in an unfavorable climate, but for most kinds of seed this is too expensive and, as in the case of other products kept in cold storage, there is rapid deterioration after it is removed from storage.

If seed is moved from a cool climate to a warm climate, or from a dry climate to a wet climate, it will not retain its vitality for long.

Seed should be kept dry and cool and should be tested before being planted.

E. H. TOOLE and E. BROWN,
Bureau of Plant Industry.

SELECTION of Honeybee Stock is Important to Beekeeper and Orchardist Among the important factors which govern the size of a honey crop are weather conditions, the acreage of nectar-producing plants, the number of colonies, the race or strain of bee, and the system of management. The beekeeper obviously has no control over the weather conditions in any locality or the acreage of plants from which his crop comes, but he can limit the number of colonies and exercise control over the race or strain, and the system of management.

Merely limiting the number of colonies would seem to be the simplest way of controlling the honey crop. Under this method of control, however, a beekeeper, in requeening, may purchase queens of another strain or race which differs in honey-producing capacity from the strain or race replaced. Furthermore, it has not been proved that the best system of management for one race is best for all. An exact knowledge of races and strains of races of the honeybee is therefore of great importance in any planned control of honey production. Such knowledge is not yet at hand, and beekeepers in this country still await the appearance on the market of strains that have been scientifically demonstrated to be practically constant in honey-gathering capacity under given conditions. An investigation now being carried on by the Division of Bee Culture of the Bureau of Entomology is making it possible

to distinguish between races and strains of races in honey-gathering capacity, in response to system of management, and in other respects.

The present inadequate knowledge of races and strains of the honeybee is not due to the American beekeeper's lack of experience with more than one race, as all the standard races have been imported into the United States. It is true that until 1861 there was only one race in this country, the Dutch or common black bee. This was brought in by early New England colonists, and there are reports that the Spaniards also brought it to Florida. Since that time all the commonly known races, the Italian, the Carniolan, the Cyprian, the Caucasian, and the German brown bee, have been brought here, and in addition such rarer races as the Palestinian, the Syrian, and the Saharan. These races are known to vary in temper, in swarming propensities, in fighting diseases and enemies, in physical characteristics, and in other respects. However, much remains to be done in the way of measuring and evaluating these differences scientifically so as to apply the results to practical beekeeping.

Races of Interest from Standpoint of Pollination

The problem of races is important to others besides the beekeeper. The orchardist, because of modern practices of clean cultivation, the cleaning up of hedgerows, forest fires, floods, and other similar factors, is faced with the loss of natural insect pollinators of his fruit. Consequently he depends more and more on the honeybee. Since the period for pollination is short and since it may coincide with cool or rainy weather, he requires a bee that will fly at lower temperatures and in cooler weather than does the honey producer. The grower of red-clover seed is turning to honeybees for the pollination of his crop, to make up for the scarcity of bumblebees. Formerly it was thought that the honeybee, because of its short tongue, did not work on red clover, but this has been found not true of certain strains at least. The growers of certain greenhouse vegetables, such as cucumbers, also depend on the honeybee for a successful crop and so need a bee that will keep its strength and vigor under greenhouse conditions. It may be that those agriculturists interested in the honeybee solely as a pollinating agent will find that the bee best suited for honey production is not the one best for pollen collecting.

Controlled Breeding Facilitates Study of Races

One of the obstacles to a study of the races and strains of the honeybee has been the fact that in nature the honeybee mates on the wing, and until recently no satisfactory method had been worked out for controlling mating under laboratory conditions. Mating can be controlled by letting queen and drones fly in isolated localities, but in view of the widespread character of beekeeping in this country there is difficulty in obtaining practicable sites for mating stations removed from all bees. The development of means of artificially inseminating queen bees, such as is offered by the Watson method, gives promise of development and improvement of honeybee races. Recent work at the bee culture laboratory has much simplified the apparatus and has provided means for quantity output of queens inseminated by this method. The manner of obtaining numerical data on physical characteristics has also been much simplified through the use of a microprojector.

Selection Important from an Economic Standpoint

The importance of using the best race for a given locality and situation, or some strain of that race, is evident even when we consider merely the amount of capital represented by the queen bees in use in the United States today. According to a recent estimate by the Bureau of Agricultural Economics, there are about 4,600,000 colonies of bees in this country, and this means an equal number of queens in active service each year. At a conservative valuation under present prices each queen is worth about 50 cents, making a total of \$2,300,000. Many beekeepers requeen every year, but even if the queens are replaced only every other year, these figures mean that new queens having a total value of more than a million dollars are put into use each year. An exact knowledge of various races and strains, coupled with scientific breeding for improved stock, should enable the beekeeper to control his production more readily and with less waste of capital than is possible under present conditions.

W. J. NOLAN, *Bureau of Entomology.*

SESAME Seeds Have High Nutritive Value; Very Rich in Calcium Sesame seeds are an important article of food in Asia, Africa, and the Near East, having been used for centuries either as a staple, or for ceremonial purposes.

Travelers in North China are familiar with the small flat rich cakes thickly coated with sesame seeds and tasting somewhat like Scotch short bread, and one of our imported delicacies is the halva of southern European countries, combining sesame with honey.

Sesame was first grown in the United States several hundred years ago by Negroes who brought the seeds with them from Africa and planted them in Georgia and South Carolina. The sesame plant naturalized itself and still flourishes particularly in the islands off the South Carolina coast and furnishes the commercial confectioners of Charleston with seeds that they use in their candies.

Until recently one of the chief merits of sesame seeds, the fact that they are extremely rich in calcium, had escaped the attention of nutritionists. Three types of whole sesame seeds (*Sesamum orientale*) analyzed last year by the Department, from seeds grown in Arizona, averaged about 1 percent of calcium. These findings confirmed those in published reports from other parts of the world in showing sesame seeds to be far richer than any of our common plant foods in this important element. They are rich, too, in protein of good quality, in fat, and in phosphorus. The seeds have a very agreeable taste, especially after roasting, and like nuts they can be used in many ways in the diet. In view of these facts sesame seeds appear to have excellent possibilities as a food, especially for use in diets that need to supply an abundance of calcium.

The calcium content of the whole seed is very much higher than that of the decorticated seed, since much of the calcium lies in the seed coat. The creamy white seed that is used to some extent by the bakers in this country is the decorticated seed imported in this form from China.

According to data compiled from various sources the percentage composition of the whole seed is about as follows: Water, 5.8; protein ($N \times 5.3$), 19.3; fat as ether extract, 51.1; total ash, 5.7; crude fiber, 3.2:

and carbohydrate by difference including fiber, 18.1. The calcium and phosphorus content of the seed is about 1 and 0.7 percent, respectively, expressed as the element in percentage of air-dry substance. No satisfactory data on iron content are available. The decorticated sesame seed contains only about 3 percent total ash, 0.08 percent calcium, and 0.68 percent phosphorus, judging by a single imported sample analyzed last year by the Bureau of Chemistry and Soils.

The nutrition laboratory of the Bureau of Home Economics has shown that whole brown sesame seed fed to rats as a supplement to a low calcium diet was effective in promoting growth and bone development. Decorticated seed used as a supplement gave poor growth, little better than that of the negative controls that received no calcium supplement.

Supply Now Chiefly Imported

At the present time, sesame is not being raised to any extent in this country as a commercial crop, but it is brought in from the East, chiefly as a source of oil. There is a market for it, as import figures show. The oil has a mild, agreeable flavor, good keeping qualities, and is used as a salad oil and for other purposes. The press cake makes a valuable stock or poultry feed. Agriculturists say that there is no great difficulty in raising it in warm climates. There is one important characteristic of the plant that has kept it so far from being a commercial success in the United States. This is the tendency for the pods to shatter as they gradually ripen, making sesame seeds hard to harvest without great waste. The California and Arizona Agricultural Experiment Stations are trying to overcome this difficulty, either by developing new varieties or by working out suitable harvesting methods, since it does not pay well in this country to harvest such crops by hand as the orientals do.

Sesame-seed recipes developed in the Bureau of Home Economics include muffins, cookies, and a brittle similar to peanut brittle, as well as directions for roasting and salting the whole seeds. Many other uses are possible in breads and cakes, or even in soups.

The newly recognized fact about the nutritive value of sesame seed should give added incentive to its production and utilization in this country.

CHARLOTTE CHATFIELD, *Bureau of Home Economics.*

SHEEP Range on Red Desert Surrounding the Red Desert railroad station, in southern Wyoming, is one of the most important That on National Forests winter sheep ranges of the Western States. Its area is approximately 11,000 square miles, or about 7,000,000 acres. The Red Desert, a high, undulating plateau, with an altitude of about 7,000 feet, lies along the Continental Divide, and is crossed and intersected at intervals by low ranges of hills. It extends from the Platte River bluffs on the east to the Green River bluffs on the west, and from the northern limit of Sweetwater County to the hills and mountains separating Colorado and Wyoming on the south.

This section is a semidesert, with an average annual rainfall of less than 10 inches. There is very little rainfall during the summer months, the heaviest precipitation occurring during March, April, and May.

This usually results in the development of all forage plants by early summer. The grasses and saltbushes cure rapidly, and the light snows permit the use of the area as winter range. Winter grazing, no doubt, accounts for satisfactory forage conditions found over most of the area (fig. 87).

The forage of the Red Desert, much better suited to sheep than to cattle, consists largely of the saltbush type, the sagebrush type, and

FIGURE 87.—Typical winter range of the Red Desert of Wyoming.

the grass type. The saltbush is probably the most important forage type of this great saline area. Sheep do not use the sagebrush contin-

FIGURE 88.—Sheep on winter range consisting of black sage, salt sage, bud sage, and salt sagebrush grass.

uously from choice, but as the leaves are evergreen, they remain fresh throughout the winter. Even in the driest seasons these plants furnish a large amount of winter forage. While many grasses occur in the Red Desert the most important are various species of wheatgrass (*Agropyron* spp.). Others include Indian ricegrass (*Oryzopsis hymenoides*), bluegrasses (*Poa* spp.), and brome-grasses (*Bromus* spp.).

Flockmasters Never in Ruinous Conflict

Local stock associations have been responsible for such control as has been in effect on this winter range (fig. 88), and although a large part of the area is public domain, there have never been any ruinous conflicts for range between flockmasters. Sheep owners have purchased the odd-numbered sections from the Union Pacific Railroad, as a large part of the area lies within the railroad grant, and have thus secured use of adjoining public domain.

The owners of the sheep outfits using this winter range control water holes, and own or control hay ranches and range lands, in the areas surrounding the Red Desert, which are used as spring and fall ranges. If the national-forest ranges were not available for summer use, however, these investments would be of little value, while the Red Desert itself would be of little use. The summer ranges are within the Medicine Bow National Forest of Wyoming and the Routt and Arapaho National Forests of Colorado to the south, and the Wyoming National Forest to the north. These high mountain areas, with their luxuriant growth of weeds and grasses, abundance of fresh water, and cool climate, furnish ideal conditions under which to handle sheep and produce both wool and lambs of highest quality.

In late April and May sheep which have been held on the winter range are taken to the adjacent foothill sections for lambing. After lambing and shearing are completed, ewes and lambs are trailed 80 to 150 miles to the national-forest ranges, where they remain for from 70 to 80 days. In September or early October they are trailed from the national forests to fall ranges similar to those used in the spring. In November or early December, depending upon the fall of snow, sheep are again trailed to the Red Desert for winter range.

Most of the 600,000 sheep using the Red Desert as a winter range use the national forests as summer ranges. No separation of values of the Red Desert as a sheep range can be made without considering the adjacent national-forest ranges. One without the other is of little value, but together these areas of northern Colorado and southern Wyoming form one of the most important range areas of the West. The sheep industry of this section is possible because of the availability of fall and spring ranges adjoining the national forests, mountain range for summer use in the forests, and winter range on the Red Desert. The Forest Service has recognized this in approving grazing preferences on the national forests. These are based on the ownership or control of fall, winter, and spring ranges within or adjacent to the Red Desert section.

HUBER C. HILTON, *Forest Service.*

SHEEP Range Supplied by National Forests in Pacific Northwest

Handling range sheep successfully in the Northwest requires that they be removed in summer from the hot, dry valleys and placed on mountain ranges, where water, succulent feed, and lower average temperatures provide favorable grazing conditions (fig. 89). This seasonal movement also allows the low ranges to produce a forage crop during the summer months for grazing use during the other seasons of the year. Spring, fall, and winter sheep range and cultivated feed crops in eastern Oregon and Washington provide for many more sheep than can be handled on the summer ranges, which puts a premium on summer range.

There are approximately 2,700,000 range sheep in Oregon and Washington. Of this number, over 1,200,000 graze under permit on the national forests in Oregon, Washington, Idaho, and Montana (fig. 90). Approximately 800,000 graze on privately owned timberlands within

FIGURE 89.—On summer range high up in the Cascade Range of Washington.

or immediately adjacent to the national forests. Indian reservations carry a considerable number, and the remainder graze on the public domain.

On ranges in privately owned timberlands and on most of the Indian reservations sheep are grazed under annual leases. National-forest per-

FIGURE 90.—A sheep camp amid the alpine firs of a national forest.

mits are issued annually or for a definite term of years. The lease price for privately owned timberlands is based on competition for the range and varies from 5 cents to 25 cents, or more, per acre, and there is little or no restriction on the number of sheep grazed. Since several acres per head are required, the cost of grazing on such lands is important.

Indian-reservation lands are leased on a competitive-bid basis, but the number of stock allowed to graze is specified.

Nominal Charge on National Forests

On the national forests, a nominal rate only is charged, while the numbers of sheep, seasons of use, and management of sheep are definitely regulated (fig. 91). On the public domain no charge is made, and

FIGURE 91.—Sheep spread out on the high mountain pastures.

there are no restrictions or regulations. Of all these range areas the public domain is of the least value comparatively. It is at a lower ele-

FIGURE 92.—Summer sheep range on the Mount Baker National Forest, Wash.

vation, and its once-valuable forage has been largely destroyed by unseasonable use and overgrazing.

The beneficial results obtained from regulated grazing are calling attention to the increasing need for conservation of forage resources. Without national-forest and other summer ranges a large part of the

range sheep in Oregon and Washington would disappear from a territory which is not suited for the production of crops other than livestock (fig. 92).

At normal price levels the sheep industry represents in the two States at least \$60,000,000 in capital investment and its annual gross income is in excess of \$20,000,000. Therefore, any condition or change that adversely affects it immediately becomes a matter of State-wide concern. The interrelation between the summer ranges and the capital investment in real and other properties in the range country is very definite, and their proper management is a high public service.

SOIL-EROSION Studies Show Vegetation Has Dominant Role

For the first time in the history of the United States, protection of watersheds and cultivated fields from costly erosion is receiving some measure of the serious attention it has merited. The President has repeatedly pointed to the necessity for doing something to control the evil. He is backing up his suggestions through the work of the Civilian Conservation Corps, part of which is being devoted to gully control and the planting of trees on strategic watershed areas.

Anyone who critically examines the situation confronting the rolling agricultural lands of the Nation, comprising fully 75 percent of all land in cultivation and an equal percentage of that on the western ranges, readily recognizes the seriousness of the problem of unrestrained soil erosion. The destruction of the fertility of 190,000 acres of formerly cultivated land in a single county and its abandonment would seem sufficient cause for at least slight alarm. That recent surveys and erosion measurements have shown that approximately 35,000,000 acres of formerly cultivated land, most of it originally good land, have been ruined by gullying is still greater cause for alarm, especially when it is pointed out that an additional area nearly four times as large has been made almost hopelessly poor by having the topsoil stripped off. Such devastation and continuing land impoverishment constitute a menacing national problem requiring immediate corrective action.

Danger of Delay

Unless effective erosion-control measures are widely adopted without much further delay, the country is going to have on its hands a domain of worn-out land—land on which the struggle for a living will eventually hold many farmers to a low level of subsistence agriculture.

Land is still being cleared in various parts of the United States on slopes so steep that the farmers confess they expect the soil to wash away to a mere geological skeleton of soil within from 3 to 8 or 10 years of cultivation. Such clearings were observed in 1933 on mountain and ridge slopes in the Tennessee Valley, some of them having declivities in excess of 70 percent. This means that the better lands are largely in use, and that in many parts of the country farmers continue to turn to marginal and submarginal lands where severe impoverishment or destruction by erosion too often is an inevitable part of their programs of land utilization.

Mechanical Means of Control

As far back as the time of Christ, walled terraces were being built to hold the soil in place. No one knows for how many centuries the aborigines of the Philippine Islands, the Ifugaos, have been growing crops on strips of steep mountain slope supported by walls made with the greatest labor. Even in this country the cotton farmers of the southern piedmont have been using hillside ditches and embankments (or terraces) as a means of erosion control for almost a hundred years. On tea and rubber plantations of the East, steplike excavations are dug into hillsides, true bench terraces, in order to protect the slopes from the overwhelming erosion otherwise resulting from monsoon downpours, while in the United States the broad loose terrace has been developed and is used extensively.

Vegetation and Erosion

For some reason man has not resorted so much to the oldest and most effective measure for controlling erosion, that is, thick-growing vegetation, such as trees and grass. The primary effort has been to get trees off the land and to destroy the matted prairie grasses so that cultivated crops might be grown. Clearing away all obstacles ahead of seeding has been the first thought of agricultural man, as well as the second and dominating thought, too generally.

Another deterrent to the use of thick-growing vegetation has been sheer ignorance. There was no clear understanding of the fundamental facts involved in erosion processes until recently. No basic studies of this most potent agency of destruction affecting the physical characteristics of the land were undertaken until a few years ago. Almost every conceivable phase of the numerous chemical and physical forces affecting soil and agriculture had been studied in some aspect except this force of erosion, the very one that should have been investigated first because it is the most deadly enemy of soil productivity.

It has long been understood that destructive soil washing rarely affects unburned forests. It was generally assumed by students of forestry that the protection involved was due to the direct capacity of the forest mold to absorb rain water, plus the binding power of tree roots. Now we find that although these effects are important, they constitute a relatively small part of the full protective force of woodland cover. The most effective function of a forest in this respect is that the vegetable litter covering the floor of all wooded areas serves not only to filter suspended soil from water flowing in from eroding areas above, wherever there are such areas, but also to physically retard direct erosion of the soil beneath. Thus, clear water is sent down into the soil by way of the natural pores and the holes formed by earthworms and decaying roots. Muddy water from eroding land quickly seals these diminutive openings; rains accumulate over this screen and flow away burdened with loosened soil.

From a controlled forested area in central Oklahoma 250 gallons per acre of clear water ran off during a continuous rainy period in May 1930; but from a similar area alongside where the leaf mold had been burned over, 27,600 gallons of muddy water ran off. The water-holding capacity of the mold on an acre of ground of the same kind was shown to be approximately 17 tons. In other words, the forest mold absorbed 17 tons of rain water for every acre and in addition

caused the absorption by the soil beneath of 97 tons per acre in excess of the amount absorbed where the vegetable covering had been burned. This filtering and protective effect of the litter thus resulted in the absorption of more than five times as much water as was soaked up by the litter itself.

The average annual losses from this area for a 3-year period have been 0.013 tons of soil per acre and 0.11 percent of the rainfall from the virgin area, as against 0.22 tons of soil per acre and 4.53 percent of

FIGURE 93.—Total soil losses and average water losses from Shelby loam (8-percent slope) for 1931 and 1932. Northern Missouri-southern Iowa erosion station, Bethany, Mo. Rainfall, 1931, 42.52 inches; 1932, 27.04 inches. All plots 6 by 72.85 feet except plot 1 which is 6 by 145.7 feet.

the rainfall from the burned-over area. In other words, the unburned forested area has held back 15 times as much soil and 41 times as much water as the burned-over area.

Soil Lost with Corn Growing

On July 1, 1933, 2½ inches of rain washed 39 tons of soil per acre from a cornfield near La Crosse, Wis. Twenty-seven percent of the rain

was lost as run-off. On the same kind of land, having the same declivity, covered with bluegrass, neither a drop of water nor a particle of soil was lost because of this same rain.

The total soil loss from an 8-percent slope of Shelby loam (one of the most important corn soils of north-central Missouri and southern Iowa) devoted to corn continuously has been for 2 years 133.8 tons per acre, as against a loss of only 0.39 ton per acre from the same kind of soil on which alfalfa was grown, having the same slope and receiving the same rainfall. The corresponding water losses were 25.8 percent from the cornland and 1.7 percent from the alfalfa land (fig. 93).

The Protective Power of Grass

The average rate of soil loss caused by erosion from the principal type of land on moderate slopes in the wheat belt of western Kansas has been 4,260 times greater where a cultivated crop (kafir) was grown than where the same kind of land was covered with native plains sod. Also, about 400 times as much water has been absorbed where the ground was well grassed. Expressed in another way, where a tilled crop is grown, 58 years would be required to wash off the 7 inches of topsoil covering this kind of land down to comparatively unproductive subsoil, as against 246,000 years to wash off the same depth of soil where grass is grown.

Strip Cropping to Save Soil

A considerable number of farmers in the hill country of Wisconsin, apparently sensing the prodigious soil-saving capacity of grass, have for a long time been practicing strip cropping to protect their sloping fields. They have left the steeper upper slopes in woods; below the woods they have planted grass along the contours, that is, in level strips across the fields rather than up and down them; and below this they have grown alternately strips of corn, grass, potatoes, grass, and so on. The grass intercepts the water flowing downhill, checks its velocity, spreads it out and causes much of it to sink into the ground, thus giving protection to the strips below.

This practice not only affords a large measure of protection from erosion but provides a balanced type of agriculture, the growing of a variety of crops. Since the grass strips often include clover, and since the position of the crops is switched from time to time, the practice also means the employment of soil-improving rotations.

To some extent Pennsylvania-Dutch farmers have used this system, which so closely conforms to nature's method of stabilizing sloping land. But few others have done so until recently. At the erosion-experiment stations throughout the country the method is being tested in various modifications, employing a large number of the thick-growing, soil-saving crops, as grasses, clovers, sorghum, alfalfa, lespedeza, peas, and so on. A combination of strip cropping with small embankments (terraces) following the contours of the fields is being tested also. One farm of over 5,000 acres in the erosive black belt of central Texas is now completely and effectively covered with this cheap, simple system of soil conservation.

Protecting Iowa Farms

During a year and a half only 1 pound of soil per acre has been lost from a large experimental field at the erosion station in southwestern

FIGURE 94. —Severe erosion on summer fallow, upper part of field, and no erosion on wheat stubble below, caused by the heavy rain of July 30, 1931, Whitman County, Wash. The dark streaks through the lower part of the field represent erosional debris from above, caught by the wheat stubble.

Iowa, where corn has been grown in alternate, parallel strips with alfalfa. The same kind of land used for corn according to prevailing

FIGURE 95. —Erosion on summer fallow, 40-percent slope, caused by the rain of July 30, 1931. Many of the small gullies go to the depth of plowing. Whitman County, Wash.

practice has lost 9 tons of soil an acre, or 18,000 times as much as that protected by grass strips. The land used in these comparisons is the best upland corn soil of the country, if not of the world, the loessial soil

of the Missouri River Valley. Under prevailing practice, soil is being swept off these indispensable lands with every heavy rain, like leaves driven before the winds of autumn.

A Permanent Cure for Erosion

Even grain stubble is a potent agency for slowing down erosion (both water and wind erosion). Heavy summer rains (as that of July 30, 1931) and melting snow cause a tremendous amount of washing on summer-fallowed steep slopes in the Palouse wheat belt of Washington, Idaho, and Oregon, but very little when the ground is covered with stubble. This effect is well illustrated in figures 94 and 95.

Vegetation in the form of forest or in thick grasslike growth is an inexpensive, permanent cure for erosion. In one form or another it can be used on all kinds of land, on any degree of slope and under all varieties of climate where there is heat and rain enough to make plants grow. Of course, all land cannot be used for forest and the thick-growing crops. We must devote large acreages to the erosion-producing, clean-cultivated crops, such as corn, cotton, tobacco, and potatoes; but it has been definitely shown that the two types of crops can be grown in conjunction with one another in such a manner as enormously to reduce soil and water losses. It now remains to educate the farmers of the Nation with respect to the advantages of the soil-protective types of agriculture. This can be done as soon as the Nation decides to adopt better farming methods, methods which call for the use of land more nearly in accordance with its adaptability and fitness and for the efficient protection of all cultivated slopes.

H. H. BENNETT, *Bureau of Chemistry and Soils.*

SOIL Survey Is the Necessary Basis of Land Classification

The agricultural readjustment, to which many leaders look for a solution of existing agricultural problems, has directed attention to the production potentialities of different parts of the country and to the necessity for a reliable inventory and classification of the lands of the country.

Economic classifications as a rule concern broad general kinds of land defined without any necessary relation to fundamental natural character. The units of such classification are defined on the basis of the possibility of profitably using such lands under the economic conditions prevailing at the time the classification is made. The groups are usually designated as marginal, submarginal, and supermarginal. These classifications may be based entirely on statistical data with no reference whatever to the character of the land. Such a classification may be called single-purpose since such classes when defined and located on the ground may be used for one purpose only. They simply define the varying degrees of marginality and offer no explanation of these variations. The data presented are not capable, through interpretation, of application to the solution of a wide range of problems.

However useful such classifications may be and however well they may fit the requirements of the term classification, they cannot satisfy the requirements of an inventory of lands.

Like a classification of any other series of natural bodies, a rational fundamental classification of soil bodies can be based only on the

characteristics of the bodies themselves. The classification discussed here is a natural classification.

Land has many characteristics. Not all of them are known, and the significance of some that are known is not well understood. It is not possible yet, therefore, to make one final classification of land applicable to all conceivable purposes. The classification here discussed is necessarily one applicable to agricultural uses. The basic agricultural use of land is for the growth of plants, mainly those plants which man has selected, because of their character, as his crops.

The term land connotes a part of the earth's surface, and for some purposes it applies merely to the existence of an area of the solid crust of the earth lying exposed to the air and sun. As an agriculturally used body it connotes an area of the solid crust with its form or relief and the condition of the air over it. It connotes climate, soil, and relief or shape of the land surface.

Preparation of Soil Map

All of these factors must be taken into consideration in any natural classification of agricultural land, but because of the different function of each factor in productivity each must be used as a basis of a classification and the resulting classifications superposed for the final result. Since classifications to be of practical use must be expressed in the form of a map, the procedure actually carried out involves the superposition of a map of an area classified according to climatic differences which affect production, another classified according to topographic differences, and a third classified according to soil differences. Climatic differences influence both kind of crop and amount of product. Relief differences concern accessibility or availability of a given area of land for agricultural operations, and soil differences concern primarily differences in amount of product. Primarily the three maps of a region to be superposed for a final land-classification map would be (1) a map of crop-adaptability regions, (2) a map of agricultural-availability regions, and (3) a map of productivity regions.

Climatic or productivity regions are large. In the United States the number may be reduced to about six, each covering therefore a large area. The construction of such a map on paper or in the mind of a student of land is a simple matter. This must be considered a first simple step in his work. The construction of an accessibility (relief) map requires more detailed knowledge of the country, for great differences of relief may be present within very small areas. Areas of uniform relief therefore are small, and such a map is extremely complex. In the United States details of relief throughout the country have not yet been determined, but enough is known to make reasonable progress in land classification possible.

Relief is not at all concerned with inherent productivity of a spot for plants. Aside from the fact that favorable climatic conditions are necessary for any plant growth at all, the climatic conditions are not factors determining differences of productivity except for large areas. Unit climatic areas are areas of relatively uniform adaptability, not areas of uniform productivity. A classification of the land area of the United States into wheatland, cornland, cottonland, grassland, and so on, could not solve the land-classification problem of the country, since that problem is concerned primarily with the thousands of productivity differences of areas within any one of the adaptability areas.

The problem of land classification is concerned with the adaptability-area map on which a greatly detailed map of different accessibility and productivity has been superposed.

Plant-Production Capacity is Primary

In a rational, fundamental, and comparative classification of land on a productivity basis the inherent natural capacity of the land for plant production must be the chief consideration. Data for such land classification cannot be obtained from statistics of productivity, since these merely express the results arising from a number of factors of which natural capacity of the land is one only. Of the three factors in the concept of land, climate and relief are mainly concerned with other matters than productivity; the only other factor, therefore, is soil, and the burden of productivity must be borne by it.

The indispensable data therefore for a land classification expressing capacity for plant production is soil data. Since plant production must take place on the natural soil, data regarding the characteristics of soils in their natural habitat are indispensable. These data must cover soil characteristics, the construction of soil units or soil types defined on the basis of definite combinations of characteristics, the distribution of each unit or type, and its area. This must be supplemented by comparative data on soil type-crop or natural-vegetation relationship that make possible an accurate interpretation of each type group of characteristics in terms of productive capacity. No such mass of data can be accumulated except through a long period devoted to the study of soils in the field. No amount of laboratory or crop-plot experimental work can supply it. The only investigations that have ever been concerned with such work are soil surveys. Soils as such have never been studied, the results accumulated, compared, interpreted, and expressed in final form in maps and discussions except by organizations engaged in the work of creating soil units and mapping their distribution in the field.

Since the character of the soil has been determined to an important extent by the character of the relief on which it has developed, the lack of detailed data necessary for the construction of a map of relief may be supplied to a considerable extent by a proper interpretation of a soil map.

That part of the work of land classification, therefore, which must be based on differences of soil productivity must rely almost exclusively on the maps and reports of the Division of Soil Survey.

Work Began in United States Many Years Ago

Fortunately this work was begun in the United States many years ago before the demand for land classification had arisen. Through cooperation in their work and participation in the expense between the Federal Bureau and State organizations in the several States of the Union, a large part of the country has been covered, and a personnel of thoroughly trained workers has been built up which makes possible the completion of any important specially required area, not yet covered, in a very short time. Only by using the accumulated results of the Division of Soil Survey is it now possible to make a natural (physical) classification of the lands of the United States on the basis of inherent natural-productive capacity.

C. F. MARBUT, *Bureau of Chemistry and Soils.*

SOYBEANS Content of Amino Acids Varies Greatly With Variety

Supplementing feeds to obtain a balanced protein ration is one of the most effective means of more efficient crop utilization, and at the same time tends to decrease the volume of crop production.

Protein is the most expensive constituent of foods and feeds. Every bag of feed, such as meals and mixed feed, is required by law in every State to be labeled with its protein content. Graduated premiums are paid for wheat according to a scale of increasing protein content. Protein is the element that produces muscle. Without enough protein of the right kind in the diet, animals will not grow, remain healthy, or reproduce.

Not all proteins have the same food value. One sack of feed may be an ideal ration, whereas another containing the same quantity of protein may be almost worthless because of the poor quality of its proteins. A protein which contains all the nutritionally essential amino acids in sufficient quantities and in a form available to meet the nutritional needs of an animal is referred to biologically as a protein of good quality. Proteins are made up of about 18 or 20 amino acids, 4 of which are essential for the growth and nutrition of animals. These are lysine, tryptophane, histidine, and cystine. When any one of these four amino acids is lacking in the diet, an animal cannot grow or be nourished satisfactorily.

Proteins in some of our most important foods are deficient and even lacking in one or more of these essential amino acids. Other proteins contain all of them in relatively large quantities. It is of utmost importance to farmers to know how to mix different feedstuffs to produce a balanced protein ration. Satisfactory utilization of foods and feeds depends on the knowledge of how to combine them so that the protein deficiency of one foodstuff can be corrected by mixing it with the proper quantity of another. In order to do this the quantity of amino acids in different foods must be known. This can be developed only by fundamental investigations on the properties and composition of proteins.

The chief proteins in many foodstuffs have been isolated in the Bureau of Chemistry and Soils, and their amino acid composition has been determined. Work is in progress on a method for determining amino acids in feedstuffs without first isolating and purifying the individual proteins. This should give a better picture of the protein value of the feedstuff in its entirety.

Recent studies in the Bureau of Chemistry and Soils on the proteins of soybeans have disclosed the fact that different horticultural varieties of the same seed may show differences in the amino acid composition. In view of the great increase in the production of soybeans in the United States during recent years, any significant difference in the food value of one variety over another becomes a matter of importance. The production of soybeans in the United States has increased from nearly 3 million bushels in 1931 to more than 16 million bushels in 1932 (1933 Yearbook). In 1931-32, more than 283 million pounds of soybeans were crushed (1933 Yearbook). After the oil was expressed, they yielded 200 million pounds of soybean cake. This press cake, or cake meal, is used for feeding as a protein concentrate. It contains from 37 to 40 percent of protein. The value of soybeans as a source of protein has long been recognized by practical feeders of farm animals.

The proteins contain all the known nutritionally essential amino acids, and are rich in lysine and tryptophane. Because some of the proteins of certain of the grains, notably corn and wheat, are deficient in these two amino acids, soybean meal is an excellent concentrate to use as a supplement to these foodstuffs. Studies made with laboratory experimental animals showed that a mixture of 1 part of soybean meal or peanut meal with 3 parts of corn meal or wheat flour is between two and three times more efficient for growth production than either corn meal or wheat flour alone, because of protein supplementation.

Few, if any, seeds have as many varieties as the soybean. W. J. Morse, of the Bureau of Plant Industry, brought from the Orient samples of soybeans representing between 2,000 and 2,500 different types and varieties. The unusually wide range of differences in the characteristics of a number of soybean varieties raised the question of whether there may be differences in the nutritional value of the protein of different varieties. Information on this point would be of importance in the selection of varieties grown for the production of seed intended for food or feed.

Significant Differences Demonstrated

Analysis of glycinin, the chief protein of soybeans, in 12 different varieties, most of them selected on the merit of their widespread popularity among the soybean growers of the United States, has shown significant differences in their composition with respect to 2 of the 4 nutritionally essential amino acids, cystine and tryptophane. The percentages in the different varieties range from 0.74 to 1.46 for cystine, and from 1.89 to 2.84 for tryptophane. Because these analyses were made on the isolated protein of the soybeans and not on the whole seed they do not give an accurate measure of the amino acids in the whole seed or meal. There are other proteins present in smaller proportions concerning the composition of which we have no information. In order to get a better picture of the protein quality of the whole seed or meal, recently developed methods have been applied for the determination of cystine and tryptophane in soybeans which give a fairly accurate picture of the amounts present in the whole seed or meal. Lysine and histidine, the other two essential amino acids, are known to be present in soybeans in adequate amounts and, therefore, have not been considered in these analyses. In table 8 are given the percentages of cystine and tryptophane in the defatted meal of several varieties of soybeans.

TABLE 8.—*The percentages of cystine and tryptophane in dry, defatted meal of several varieties of soybeans*

Variety	Cystine	Trypto- phane	Variety	Cystine	Trypto- phane
	Percent	Percent		Percent	Percent
Herman.....	0.49	1.13	Korean varieties:		
Mammoth Yellow..	.33	1.02	No. 82284.....	0.476	1.17
Tokyo.....	.34	1.00	No. 85127.....	.473	1.12
Peking.....	.39	.93	No. 85104.....	.407	1.09
Illini.....	.29	1.03	No. 85123.....	.349	.93
Chiquita.....	.32	.91	Japanese varieties:		
			No. 80459.....	.396	1.11
			No. 85667.....	.389	.95

The first six varieties listed in the table, which are among the most popular grown in the United States, show differences in their cystine content which are significant from the standpoint of their protein nutritional value. For example, the Herman variety contains more than one and three fifths times as much as the Illini variety. The six listed last in the table represent varieties of Korean and Japanese soybeans which have not yet been grown in the United States, except on an experimental basis. Their relatively high cystine and tryptophane values are of interest in case they prove to be adapted to the soil and climatic conditions in the United States.

Bureau of Chemistry and Soils.

SPRAYING Wild Host Plants in California Reduces Beet Leaf-Hopper Injury During the past two seasons entomologists of the Department of Agriculture and of the beet-sugar companies in California have been carrying out a program of spraying against the beet leaf hopper that

FIGURE 96.—A typical valley in the San Joaquin Coast Range foothills, showing the shrubs that are sprayed for the control of the beet leaf hopper.

is a departure from ordinary practice in materials, method, and location. Commonly the spray is applied directly to the crop to be protected, but in this case the spraying is being done at least 100 miles from the crop, on the wild food plants of the leaf hopper. Spraying is done in the fall before the beet crop is planted, to kill insects whose progeny would cause damage the following spring.

The beet leaf hopper carries a disease known as "curly top" of beets, and transmits it to the plant when feeding. This insect carries the same disease to tomatoes, white beans, and cucurbit crops. The leaf hopper winters in the dry inner foothills of the Coast Range on the west side of the San Joaquin Valley (fig. 96). A generation is pro-

duced in the spring which flies from the foothills into weed areas in the San Joaquin Valley and into the sugar-beet fields in the Sacramento Valley. Several more generations are produced during the summer. In the fall the leaf hoppers fly from the lowlands to the foothills.

Many attempts have been made to control the leaf hoppers in the beet fields, but none has proved effective. Because of the disease which it carries, an infected insect can seriously damage a beet plant in a single feeding, and one leaf hopper may feed upon and infect several plants in a short time. A small number of leaf hoppers can therefore spread a great deal of disease, and for this reason an effective control in the beet fields must be applied immediately after the spring flights and must be capable of eliminating the pests almost entirely.

Where the Beet Leaf Hopper Breeds

The beet leaf hoppers breed throughout the San Joaquin Coast Range foothills, but a study of their flights has shown that only those bred in the northern and central portions fly far enough north to reach the beet fields in injurious numbers. Spraying has been limited to these more important breeding areas.

As the summer is rainless in this section, there is very little green vegetation available when the leaf hoppers return in the fall. Patches of perennial shrubs and herbs growing in the bottoms of dry washes form most of the food supply. Such patches, usually only a few acres in extent, are scattered all along the foothills, and the insects gather upon them in large numbers and remain until the rains sprout their winter food plants. The total area of these patches within the spraying zone is about 10,000 acres. This entire acreage does not necessarily have to be sprayed in any one season, as leaf-hopper populations vary from year to year in any particular place. In 1931 about 4,000 acres were sprayed, and in 1932 about 6,000 acres.

How the Spraying is Done

As the area to be sprayed is uncultivated and is located at some distance from a base of supplies, it is important that the spray equipment be ruggedly built and that the materials used be concentrated.

A solution of concentrated pyrethrum extract in diesel-engine fuel oil is used. This is similar to commercial fly spray, but much cheaper, as the oil is not highly refined. The oil is sprayed from atomizing nozzles with compressed air, as a rather fine fog. This type of nozzle will distribute 6 to 7 gallons of concentrated spray per acre. The compressor and oil tank are mounted on a truck with dual wheels and large tires. For spraying large areas of low, fairly dense vegetation, a hood is mounted on the front of the machine to confine the spray from several nozzles. For spraying scattered vegetation, individual nozzles attached to long leads of hose are operated by men walking beside the machine. From 2 to 4 leads have been used, covering a strip 50 feet wide.

Because of variations in leaf-hopper abundance, it is necessary that the populations be estimated and the spray directed only to those areas that contain sufficient leaf hoppers to warrant spraying. No attempt has been made to eradicate the insects in one locality, but rather efforts have been directed toward reducing populations at all points to a relatively low level by spraying where the leaf hoppers are most abundant.

Results of Two Seasons' Spraying

Excellent kills are obtained with these machines, averaging between 85 and 90 percent of the leaf hoppers in the areas sprayed. Many areas having small populations are not sprayed, but in each of two seasons it has been possible to obtain a reduction of more than one half in the total population entering the foothills. This means essentially the same reduction in the number of leaf hoppers that fly into the beet fields the following spring.

The work in the fall of 1931 undoubtedly checked an incipient outbreak, and saved the sugar-beet industry many times its cost, which has been about \$12,000 per year. The results of the second season's work were not so obvious, as the number of leaf hoppers entering the foothills was rather small, so the damage would have been slight if no spraying had been done. The hoppers were further reduced in numbers by spraying, and it was difficult to find either leaf hoppers or diseased beets over most of the beet area the next spring. About 50,000 acres, producing approximately 800,000 tons of beets, were protected. A saving of 1 percent on this crop amounts to \$40,000. In these days when farm profits depend upon obtaining the utmost value per acre, this protection against curly-top damage has, in many instances, changed a probable loss to a slight profit. There has been a corresponding saving to growers of tomatoes and cucurbits in the sugar-beet area. In 1932 these crops suffered severely in the San Joaquin Valley, which was not protected, while unusually slight damage occurred in the area protected by leaf-hopper control.

The effects of the spraying appear to be cumulative, and the leaf-hopper breeding grounds are not producing so many hoppers per unit area as in the years before the spraying was started. If this continues, the cost of the annual spray program, as well as the chance of serious outbreaks, will be reduced.

It is probable that, with further experience, the program will be somewhat modified. Field work has shown that leaf hoppers concentrate upon small areas of winter host plants after the rains come, so spraying can be continued rather late into the winter. Some such spraying has been done experimentally and has proved effective.

WILLIAM C. COOK, *Bureau of Entomology.*

SUGAR-BEET Seed Grown Successfully in America by Overwintering in Field

The sugar-beet crop has long been unique among American agricultural crops because of its almost complete dependence upon Europe for its annual supply of seed. A shift from this traditional situation seems now definitely under way as the American industry takes advantage of new research developments of the United States Department of Agriculture. By discovering more efficient methods of seed production adapted to American economic conditions and by producing a new disease-resistant variety of sugar beets, the Government scientific work has changed the viewpoint in the industry as to sugar-beet seed and created a new demand, thus starting activities on the part of the industry that will check the flow to European seed producers of money from the pockets of American farmers.

The record of sugar-beet seed importations for the years 1911-33, in comparison with the acreage harvested, is of interest in showing the volume of seed imported and the fluctuations during the period (table 9).

³ Preliminary.

Seed Produced in United States in 1887

Since 1887, when the late Harvey W. Wiley reported successful production of sugar-beet seed in the United States, the Department and individuals in the industry have urged the desirability of domestic production of seed adapted to the various American sugar-beet regions. No practical progress was made toward producing new kinds of beets suited to American environment, and little was done by the young industry, the foreign supply being accepted as satisfactory. The impetus needed, namely, the development of beets definitely superior to foreign kinds when grown in the United States, was lacking. Experimental work of the Department in seed production became of special service, however, when this foreign supply was largely cut off during the World War. Beet-sugar companies were forced immediately into seed production to provide for a greatly expanded acreage. Serious shortages of seed limited the acreage of beets that could be planted for sugar production. Because of the haste with which the new seed-production ventures had to be pushed, many losses were incurred, yields of seed in many cases were low, and costs per pound were correspondingly high. The methods employed for seed propagation were closely patterned after the conventional European practices, but with little or no effort to improve quality or to obtain new strains of beets that might endow the enterprise with intrinsic value and permanence. Roots were grown in one season, lifted, siloed over winter, and reset the following spring. Because of high labor costs for the hand operations involved, and of losses of roots in storage pits by freezing, rotting, or drying, the methods followed were expensive. Yields ranged from a few hundred to about 2,000 pounds per acre, with 800 pounds representing a fair average. But the most discouraging feature was that, in

spite of heavy expenditure of time and money, and a large acreage devoted to seed production, the quantity of seed resulting was relatively small.

Accordingly, at the close of the war period the sugar industry, while recognizing the desirability of a controlled seed supply, turned with relief to its former sources of seed as a simpler and more economical way of securing its annual supplies. From then until now all but a small portion of the seed used in the United States has been imported, about 70 percent coming from Germany. A few American companies have maintained a portion of their seed-production enterprise, continuing to produce a small percentage of their annual needs. One large company, using the conventional method, produced seed in the 1932-33 season on nearly 500 acres planted to "stechlinge," with an estimated yield per acre of 1,300 pounds.

Overwintering Method Succeeds

Experiments of the Department of Agriculture, begun in 1922 and carried on in cooperation with the New Mexico Agricultural Experiment Station, have

shown that sugar-beet seed can be produced successfully in the southwestern part of the United States by taking advantage of the mild winter conditions and overwintering the beets in the field, thus avoiding lifting, storage, and resetting of the roots. This work has shown that sugar-beet seed, planted in 22-inch rows in highly fertile soil in early September,

FIGURE 97.—Harvesting sugar-beet seed in New Mexico from plants overwintered in the field. Contrasted with conventional biennial methods of beet-seed production, shorter occupancy of land and economies in labor requirements are outstanding advantages.

ber, 18 pounds of seed per acre, gives a growth of plants large and sturdy enough to withstand in the field the winter conditions. The plants are left unthinned in the rows, and unless the field is very weedy only machine cultivation is required. Enough irrigations to keep the plants growing are given. When blooming begins in May or June, the irrigations are given at weekly intervals. Cutting, shocking, threshing, and cleaning follow the usual procedure (fig. 97). Yields greatly in excess of those obtained with the conventional method in other parts of the United States or reported from Europe have been obtained consistently. Since 1928 commercial trials on a scale large enough to permit accurate judgment have been made, so that it may safely be said that these highly satisfactory yields have been maintained.

In southern Utah and southern California similar experimental work carried on by the Federal Department has shown that these areas are also available for producing beet seed by the overwintering method. The method, involving as it does a minimum of hand labor, and pro-

viding a rapid means of increasing a small supply of seed to a large quantity by two successive multiplications, apparently meets the problems previously encountered in producing sugar-beet seed in the United States.

Method Used to Produce U.S. No. 1 Seed

The new method was promptly put to service in making available to growers the results of the investigational work on the curly-top disease by which the curly-top-resistant variety of sugar beets, U.S. No. 1, was developed. A few hundred pounds of the seed of this resistant variety have been increased under supervision of the Department of Agriculture by interested commercial companies, approximately 22,000 pounds being harvested in July and August 1932. From this seed stock a further increase on approximately 450 acres was made in the 1932-33 season, when the yield approximated 1,100,000 pounds. This large supply of the U.S. No. 1 variety, adequate to plant 55,000 acres, will be used by growers in the 1934 season. Since the new variety is fairly resistant to curly top, it should, under all but the most extreme conditions, produce a satisfactory crop in spite of the disease. The experimental results show that under moderately severe conditions it maybe expected to outyield the European brands at least 4 tons per acre. Under noncurly-top conditions the variety apparently may be exceeded slightly in tonnage by commercial brands, but the U.S. No. 1 variety apparently has a higher sugar percentage, thus practically compensating for the tonnage difference.

In addition, strains of sugar beets known to be highly resistant to leaf spot have now been found, and tests of these strains and the production of foundation stocks are actively under way. The two coordinated projects emphasized by the Department—development of disease-resisting strains of beets to meet problems peculiar to America, and drastic modification of seed-production methods as a device to avoid the impact of foreign cheap labor—have gone hand in hand to permit the first stride forward on solid ground of an important new industry.

Bureau of Plant Industry.

SWINE Erysipelas is More Easily Diagnosed by a New Blood Test

Contributing to progress in the eradication and control of livestock diseases, investigators of the Bureau of Animal Industry have found a new means of diagnosing swine erysipelas. This disease, which is prevalent in Europe, has been increasing in several States. It was first reported in the United States in 1921, by the Bureau of Animal Industry, United States Department of Agriculture, when the causative organism was isolated from skin lesions of the so-called "diamond-skin disease". Subsequently isolated cases of the disease in the acute form were encountered from time to time, but no distinct outbreaks of this malady were recorded until 1927, when acute swine erysipelas was detected in swine herds of South Dakota. Many animals were affected in the South Dakota outbreaks. More recently the disease has been found to exist in a number of States, particularly in the Middle West. Positive laboratory tests have been made of tissues gathered in outbreaks discovered in Colorado, Iowa, Nebraska, Illinois, Ohio, New York, and the

same causative organism has been recovered from enlarged joints of lambs in Montana, Illinois, and California. An outbreak in Saskatchewan, Canada, has also been reported.

The occurrence and character of the disease in South Dakota have afforded an excellent opportunity for a detailed study of the disease as it exists in this country. In that State during 1932 and 1933, outbreaks occurred in many of the counties east of the Missouri River and in two counties west of the river. The outbreaks were sporadic except during the spring of 1932, when in two districts they were widespread, especially among suckling pigs. During the spring of 1933, outbreaks were scattered, occurring principally in older swine.

The Disease Is Contagious

Recurrences of the disease on the same farms at yearly intervals, and sometimes longer intervals, indicate the enzootic character of the infection. It seems apparent from the reports of swine raisers that this disease existed on certain farms in South Dakota for a considerable period before it was recognized. The restocking of premises occupied more or less recently by animals affected with the disease has in many instances been followed shortly by outbreaks. Outbreaks have been observed also to occur in herds shortly after the addition of one or more animals which showed evidence of the disease in the chronic form. Observations point very clearly to the fact that infection is spread through contact of diseased and susceptible healthy animals.

Although swine erysipelas may attain marked virulence under herd conditions, it has been found very difficult to reproduce the disease experimentally in its typical form, regardless of the material or methods used in the exposure tests.

The uninterrupted course of the disease presents an acute and a chronic stage. The acute stage begins with high body temperatures, 106° to 108° F. or more, with only slight indisposition or change in normal habits. These manifestations ordinarily escape notice, but may be observed in cases where the disease can be studied in its spread through different herds or different lots of a herd. In the latter part of the acute stage there may be complete prostration, followed by sudden death. On the other hand, the disease may progress into the chronic stage without showing well-marked clinical symptoms. In the greater number of cases, however, clinical manifestations of diagnostic value rapidly develop in the latter part of the acute stage.

The mortality of this disease is comparatively high in some herds, and additional losses to herd owners result from the effects of the disease in the partially recovered animals, especially deformities, which frequently develop during the chronic stage.

In general, a post-mortem examination of an affected animal reveals the lesions of acute septicemia as evidenced by congestion and hemorrhage in certain organs and tissues with some specific changes attributable to swine-erysipelas infection. These changes are not sufficiently constant, however, to make them of distinct diagnostic value early in the acute stage of the disease. Until recently the veterinary practitioner was obliged to rely entirely on the herd history, clinical manifestations, and post-mortem findings, in making a diagnosis. He was often confronted with perplexing difficulties because of similarity of certain of the clinical manifestations and post-mortem lesions of other common swine diseases, as, for instance, hog cholera or infectious enteritis, which occur frequently as a complication in swine erysipelas.

Methods of Testing

The difficulties experienced by veterinarians in the field in differentiating between acute swine erysipelas and hog cholera, both clinically and on post-mortem examination, indicated the need of some kind of test that would aid in making definite diagnoses. Recent investigations in the pathological laboratory of the Bureau of Animal Industry have resulted in the development of an agglutination test of two types. One of these is a rapid agglutination tube method and requires the use of a laboratory in making a diagnosis. The other is a rapid, whole-blood or plate test (fig. 98). It requires but little equipment and, therefore, may be used by veterinarians in the field.

Each method requires a small sample of blood from the animal to be tested. The sample is then treated with a diagnostic agent known as antigen, which causes a definite reaction in the blood of an affected animal; the blood from a healthy animal shows no reaction. The technic of the plate test is similar to the rapid-blood test for pullorum disease of fowls. The antigen used for these tests is made from broth cultures of the swine-erysipelas organisms which are killed during the process of preparing the antigen. These methods, when carried out by veterinarians who are familiar with the technic, have been found very helpful in diagnosing swine erysipelas, both in the laboratory and in the field. The test is still considered, however, to be in the experimental stage, and more information is desired from the field on a large scale before the test can be advised for general use.

FIGURE 98.—Positive and negative results obtained by the rapid whole-blood test for swine erysipelas

A reaction to the test does not eliminate the possibility of hog cholera. Also, an animal that has once had erysipelas will react to the test for a period of time following the infection. Thus a hog that has recovered from erysipelas and is showing symptoms of hog cholera may show a positive reaction to the agglutination test. For this reason the attending veterinarian must have some information concerning the history of the herd from which the reacting animal came.

Procedure for Checking Spread of Infection

Swine owners are primarily concerned in checking the spread of the infection through herds. This can be accomplished, in some cases, by such sanitary measures as the separation of healthy animals from sick ones and the removal of these healthy animals to noninfected quarters, preferably clean pastures. This procedure is recommended even when specific treatment is to be used.

Hogs that are known to have swine erysipelas may be treated with a biologic known as anti-swine-erysipelas serum. It resembles anti-hog-cholera serum in appearance and has proved highly beneficial if administered early in the acute stage of the disease. Infected herds

in which a high percentage of animals display acute symptoms may return to normal after serum treatment without the development of chronic manifestations. This serum is of very little value, however, when used in the chronic stage of the disease, and it is not recommended for use in such cases.

Swine erysipelas as a herd disease is apparently rather firmly established in certain sections of our country and presents a problem that deserves close attention. The Bureau of Animal Industry is studying the disease both in the field and in the laboratory. Experimental treatments are being conducted to determine with greater exactness the value of the serum and the limits of its practical usage. Success in combating the disease depends on close observation by swine breeders, veterinary practitioners, and livestock sanitary officials in order that outbreaks may be promptly detected and proper steps taken for their eradication.

C. H. HAYS and C. F. HARRINGTON,
Bureau of Animal Industry.

SWISS-CHEESE Making Depends Greatly on Control of Bacteria

Bacteria are indispensable in the manufacture of Swiss cheese, but bacteria are also responsible for many of the defects in the cheese as well as for many of the troubles encountered in its manufacture. It is highly important therefore that the cheesemaker carry out all of the manufacturing processes (in the kettle, in the press, and in cold and warm cellars) in such a way as to insure the growth of the desirable bacteria, at the proper time and in the proper sequence, and to limit the growth of undesirable bacteria.

The cheesemaker attempts to carry out all these manufacturing processes properly, but unfortunately he usually does not know enough about the numbers of bacteria, the kinds, or their activity in the milk, in the starters, or in the cheese to be regularly successful in making good cheese. Too often he relies on rule-of-thumb methods worked out and handed down by generations of cheesemakers, and he hopes that he has used the right combination of milk, starters, and methods of manufacture.

The modern "culture method" of Swiss-cheese manufacture, however, which was developed by the Bureau of Dairy Industry after many years of investigation to establish the relation of bacteria in the manufacture and ripening of Swiss cheese, enables the cheesemaker to select the procedure to follow under the conditions at his factory.

In using this method the cheesemaker tests the milk to determine the number and kinds of bacteria in it. He thus obtains an idea of the ripeness of the milk and determines whether undesirable gas-forming bacteria are present in large numbers. He prepares pure cultures of bacteria for his "starters", one of a thermophilic or high-temperature streptococcus called *Streptococcus thermophilus*, and one of a lactic-acid forming, rod-shaped organism or lactobacillus, called *Lactobacillus bulgaricus* or *L. casei*. He adds these starters to the kettle milk. He grows and uses these starter bacteria in accordance with the results of tests made on the milk in the morning and on the cheese made the previous day. He also adds to the milk in the cheese kettle a pure culture of a lactate-fermenting, rod-shaped bacterium

called *Propionibacterium shermanii*, furnished by the Bureau of Dairy Industry.

The cheese kettle now contains the desirable starter bacteria, other bacteria that have little or no influence on the cheese, still other bacteria that may prove helpful if properly controlled or harmful if not controlled, and finally undesirable or harmful bacteria. Work in the Bureau of Dairy Industry has shown that of the starter bacteria, only the thermophilic streptococcus grows during the manufacturing processes in the kettle. Results have indicated that the growth of this starter organism helps restrain the growth of undesirable bacteria if the latter are present in moderate numbers.

The ordinary lactic acid bacteria of milk, such as *Streptococcus lactis*, and the gas-forming bacteria grow well if they are present in large numbers in the original milk. A limited growth of lactic bacteria in the milk before and during the manufacturing processes in the kettle gives a "ripeness" that may shorten the time of manufacture and may improve the quality of the cheese. Too much activity by these organisms will result in a cheese of poor quality with poor eye formation and with "glass" or cracks in the cheese. The presence and growth of large numbers of gas-forming bacteria, especially those of the *Aerobacter aerogenes* type, is likely to result in "blowing up" or "bloating" of the cheese on the press, or defects in the cheese later.

Effects of Heating in Manufacturing Process

During the manufacturing process the contents of the kettle are heated to 53°-56° C. (128°-133° F.) and held at that temperature, usually for about 30 minutes. Then the curd is dipped into the hoop on the press table, where it is kept well wrapped with cloths to prevent its temperature from dropping rapidly while the whey is draining from the cheese. This long exposure to a high temperature kills many of the bacteria. If the starter bacteria have not been properly prepared they will be killed or weakened and will be unable to do their work at the right time in the cheese; then other bacteria may grow, with results deleterious to the cheese. The *Streptococcus thermophilus* bacteria grow during all processes in the kettle and are the first to be active in the cheese on the press. If a properly prepared starter has been used, the streptococcus will not only grow during the processes in the kettle but will grow during the first 8 or 10 hours on the press and gradually increase the acidity of the cheese during this time. Methods have been developed for measuring the increase in acidity to obtain information in regard to the activity of the thermophilic streptococcus. The rate and amount of drainage of the whey from the cheese is influenced greatly by the activity of the streptococcus in the cheese during the early hours on the press.

A properly prepared *Lactobacillus bulgaricus* culture, when used as a starter culture, begins growth in the cheese after it has been on the press for 8 to 10 hours and continues to grow and increase the acidity until practically all of the milk sugar or lactose in the cheese has been broken down, chiefly to lactic acid. A poor starter culture will begin growth much later than a good culture, will produce acid too slowly, and will leave much unchanged milk sugar in the cheese after 21 hours on the press. *L. bulgaricus* should pick up the conversion of milk sugar to acid about the time that the growth and action of *Streptococcus thermophilus* begins to slow down.

The temperature of the cheese on the press has considerable influence in determining when the starter bacteria will begin to develop. The temperature of the freshly dipped curd may be high enough to slow down the action of even the high-temperature streptococcus. The rod-shaped or lactobacillus starter bacteria do not begin to grow until the cheese has cooled down sufficiently. *Lactobacillus casei* can start growth at a higher temperature than can *L. bulgaricus* and usually begins to grow after the cheese has been on the press for about 5 hours. This difference in the two kinds of *Lactobacillus* starters is used in a practical way. *L. casei* is useful in helping to keep down gas-forming bacteria when they are present in large numbers. The more slowly developing *L. bulgaricus*, however, is preferable with good milk; for a cheese with better texture and flavor is likely to result.

Action of Starter Bacteria of Great Importance

The action of the starter bacteria on the cheese in the press is of great importance in determining the quality of the finished product. The early action of the *Streptococcus* keeps down the growth of undesirable bacteria, controls the draining of the whey from the cheese, and carries on the destruction of milk sugar with the formation of lactic acid until the *Lactobacillus* takes up the work. The *Lactobacillus* continues the decomposition of milk sugar until it has all been destroyed and at the same time suppresses the growth of undesirable bacteria. Both kinds of starter bacteria influence the texture of the cheese in the press and later on, and both have an influence on the eye formation and flavor development which takes place later in the cheese. These bacteria finish their growth soon after the cheese leaves the press, but even after their death, the enzymes from their cells continue to act on the cheese.

After the starter bacteria have completed their work, no fermentable sugar remains in the cheese, for the milk sugar has been converted to lactic acid which acts on some of the salts of the cheese to form salts of lactic acid called lactates.

After the removal of the cheese from the press it is held in the cold room at 10° to 15° C. (50° to 60° F.) for 10 to 14 days, during which time the cheese is salted by immersion in the brine tank or by having salt rubbed on the cheese surface. The salting lasts only 2 or 3 days. The cheese cools, and any growth of starter bacteria that might have continued is stopped.

The cheese is then removed to the warm or fermentation cellar, which is held at about 23° C. (72° F.). There the bacteria able to ferment lactates do their work, with the consequent production of eyes and a characteristic flavor. Certain species of these bacteria are able to change the lactates to propionic acid, acetic acid, and carbon dioxide gas, together with small amounts of other substances. The texture of the cheese should by this time have become rubbery, and the gradually formed carbon dioxide gas should collect in the cheese and blow spherical holes or "eyes" in the rubbery cheese curd. When the cheese-maker judges that these eyes have developed sufficiently he moves the cheese back into the cold room and thus slows or stops gas production by the lactate-fermenting bacteria.

Three Types of Bacteria Predominate

Many kinds of lactate-fermenting bacteria have been found in Swiss cheese, but work in the Bureau of Dairy Industry has indicated that three types usually predominate. Usually the first to appear is a rod-shaped bacterium which resembles a *Lactobacillus* in many ways. These bacteria often grow considerably in the cheese on the press and reach large numbers before the cheese is taken to the cold room. Maximum numbers are present just before or at the time of the start of eye formation, and thereafter there is a gradual decrease in numbers. They are followed by a spherical organism, which usually occurs in groups of four cells and is therefore termed a tetracoccus. The tetracoccus attains maximum numbers before the development of eyes is complete and gradually decreases in numbers thereafter. The third lactate-fermenting bacterium to appear in large numbers is *Propionibacterium shermanii*, which was added with the other starter bacteria to the milk in the cheese kettle. This organism usually increases slowly during the first weeks in the warm room and only reaches maximum numbers at the time the eyes are fully formed or later. This bacterium apparently has little to do with the start of eye formation but may help to increase the size of the eyes; it is most important, however, in the development of the characteristic Swiss-cheese flavor. The tetracoccus and the lactobacilluslike rod are usually the ones chiefly concerned in eye formation. Experiments have shown that eye formation takes place in the absence of *P. shermanii*, but that the cheese does not have the characteristic flavor of good Swiss cheese.

When the cheese is moved from the warm room to the cold room it cools slowly, the lactate-fermenting bacteria have a slower rate of growth, the cheese loses its rubbery texture, and becomes more crumbly or "shorter." In the cold room the enzymes released from bacterial cells continue to function, and the flavor and texture improve. Up to certain limits the longer the cheese is held, the farther the ripening proceeds. In Switzerland the cheesemakers usually hold their cheese until it is 5 or 6 months old.

The addition to the milk of too many of any of the bacteria important in cheesemaking will cause troubles or defects in the cheese. Too many thermophilic streptococci will cause too rapid drainage of the cheese in the press and produce too many eyes in the cheese. Too many lactobacilli and too few thermophilic streptococci produce a cheese with few and small eyes and cracks in the curd. Too much *Propionibacterium shermanii* culture causes too many eyes in the cheese; too few of these bacteria mean a cheese which lacks in flavor. Too many of the other lactate-fermenting bacteria give the cheese an undesirable flavor and may cause too many eyes. Use of cultures of the proper organisms under conditions which insure their optimum numbers at each stage of development of the cheese gives the best product. It is the object of the pure-culture method to insure that desired balance of kinds and numbers of bacteria.

W. C. FRAZIER, Bureau of Dairy Industry.

TAX Relief for Farmer Touches Public-Finance Problem as a Whole

Farmers have sought for years to reduce farm taxes by shifting a part of the cost of government from themselves to shoulders more able to bear it, but their efforts have not been conspicuously successful. Average farm real estate taxes per acre of all land in farms in the United States increased from 51 cents in 1920 to 58 cents in 1929, and at no time during the period was there a decrease.

After 1929 the tax declined until in 1932 it stood at 46 cents per acre, or 22 percent below the 1929 level. This reduction followed closely and resulted principally from a collapse of prices. While average farm real estate taxes per acre were falling 22 percent, the index of farm prices declined 59 percent and the tax per \$100 of value increased 26 percent because the fall in land value was greater than the fall in taxes. Hence, the burden of farm taxes was not reduced; it was increased. Furthermore, the reduction in tax per acre was brought about chiefly by curtailing services and reducing salaries of school teachers and other public servants.

Though during the last 3 years there have been new and additional levies upon gasoline, general sales, and income, the revenues therefrom have been used mainly to meet the need for emergency expenditures and otherwise to help balance budgets. In States in which these taxes were used to replace a part of the property tax, it appears that the substitution has also served partly to reduce pressure for budget cutting rather than entirely to reduce property taxes.

Failure to reduce farm taxes greatly by revision of the revenue system does not mean that it is impossible, nor does it mean that farmer efforts to shift a part of the tax burden have failed. The farm-tax problem, broadly interpreted, is not merely a tax-reduction problem; it is also a problem of how to reduce the farmers' share of total taxes. If the introduction of a new source of revenue prevents farm taxes from rising to otherwise higher levels, or makes available to farmers desirable governmental services they otherwise would not receive, nonfarming groups are at least assuming an increasing share of the total tax burden. Thus interpreted, the farm-tax problem relates not only to the cost of governmental service but also to the quantity and quality of such service; it becomes the whole field of public finance from the point of view of the farmer.

Farmers' Interest in Governmental Economy

Besides an interest in reducing his share of the cost of government, farmers have the same interest in governmental economy as have all taxpayers. The stress of economic depression has forced a reduction in public expenditures, but has only slowly brought to public attention the fact that it makes a great deal of difference by what methods the reduction is brought about. Apparently there are at least three general ways for local governments to economize: (1) By curtailing services, (2) by reducing salaries of public servants and avoiding the payment of unreasonable prices for materials purchased, and (3) by consolidating governmental units and centralizing administration. The first two of these three methods have been used generally during the last 3 years; the third has been used little but has been much discussed.

Public authorities and students of public finance point out the need for reallocating functions among the various units of local government

and the State, and for reducing the number of units by consolidation or other means. It is contended that such changes would afford a great opportunity for either a reduction of farm taxes without any impairment of present services or an improvement in services without an increase in taxes.

To test this contention, the Bureau of Agricultural Economics is assembling facts for representative local-government situations. The first study was made in Washburn County, Wis., in cooperation with the Wisconsin Agricultural Experiment Station. Results indicate that 10 percent of the cost of local government could be saved by: (1) Substituting a rural county-unit school system for the present district system, (2) transferring township-road administration to the county, (3) consolidating the county with two adjoining counties, and (4) consolidating or abolishing townships. If the possible savings from these changes should be used entirely to reduce local taxes, the farmers' tax bill might be reduced as much as 20 percent. This arises from the fact that a large proportion of the cost of local government in Washburn County is derived from State aids. It is highly questionable, however, that the aids would or should remain unchanged; and it is even more doubtful that all the saving would be used to reduce taxes. There is at least a good chance that a part would be used to improve services. The conclusion, therefore, is that although the possible savings from these adjustments are important, the extent to which farm taxes would be reduced is somewhat open to question.

Objections Raised to Centralization

Inertia is the principal reason local government is not likely to be reorganized quickly. The existing system is old, the people are accustomed to it, and the vast majority have given little thought to the possibility or desirability of changing it. Among those who have given thought to the matter, some are not sure that to do without the possible saving is too high a price to pay for retaining the present system. Home rule, it is claimed, is worth something. Many readily admit that the present system at its best is less efficient than the more centralized form might be, but they question whether it is less desirable. Furthermore, they are not sure that the possible savings would actually be realized. It is pointed out, for instance, that there is no guarantee that any form of government will be more efficient than any other form; and that although the more centralized forms offer possibilities for greater efficiency, they may easily become the more burdensome to taxpayers if controlled by persons whose actions are not motivated by high ideals of public service.

The Wisconsin study should be supplemented by similar studies in other areas, and the possibilities of even more radical changes should be considered. State centralization of the school system, as recently adopted by North Carolina, is an experiment that is being watched everywhere with interest. Perhaps State centralization is a more hopeful method of reducing costs than is consolidation of local units. State highway systems, for example, might be further enlarged to include more of what now constitutes the county and township systems. Virginia and North Carolina have transferred the administration of county highways to the State. A promising intermediate step was taken by Indiana when it transferred the administration of township roads to the county.

By whatever means the efficiency of local government is increased, State action is likely to be involved. This is especially true in States in which a large part of the local costs is defrayed by State aids. State-aid laws will have to be so revised as not to prevent desirable action on the part of any local unit. In Wisconsin, local units could not at present make the proposed changes analyzed in the reported study without a loss of State aids amounting to more than the possible savings from reorganization. The character of the revisions in State-aid laws will depend upon State policy. Revisions may be such as to force action on the part of a reluctant minority of local units, or they may merely remove existing barriers to possible voluntary local action.

Bureau of Agricultural Economics.

TERRACES Effective for Controlling Erosion on Cultivated Land

A large part of the crop land of the United States must be protected from the erosive action of rainfall if it is to remain permanently in profitable production. Erosion is not uncommon on ground slopes of less than 5-foot fall in a distance of 100 feet; yet in some places lands of 10 times this

FIGURE 99.—A broad-base Mangum terrace. With terraces of this type, the whole field can be planted to a clean-cultivated crop and farmed as a unit.

degree of slope are being cultivated. Tillage destroys the natural vegetal protection and loosens the soil so that it is especially susceptible to erosion. The fertile topsoil must be held on the field by protective measures that interfere as little as possible with the cultural operations necessary to keep the soil in suitable condition for plant growth and to control weed and insect pests.

That terracing is a practical and effective method of controlling soil erosion, whereby all of the land in a field can be safely cultivated, has been demonstrated on the Department's soil-erosion experiment

stations (fig. 99). At the Red Plains station, near Guthrie, Okla., the loss of soil during 1932 from an unterraced area with a slope of about 5 percent was 88 tons per acre, whereas the loss from a terraced area with about the same land slope was 4 tons per acre. Both areas were similarly cropped, being fallow until May 15, in cotton until October 15, and in winter wheat the remainder of the year. The rate of soil loss from the terraced area was only $4\frac{1}{2}$ percent of that from the unterraced area. On the experiment farm at LaCrosse, Wis., terraced land planted to barley lost less than 150 pounds of soil per acre during two rains totaling $3\frac{1}{2}$ inches, and the unterraced land similarly cropped lost 3.56 tons per acre, the loss from the terraced land being 2 percent of that from the unterraced land. Land planted to wheat at the experiment station near Bethany, Mo., lost, during one rain of 1.17 inches, only 60 pounds of soil per acre from the part protected by terraces but lost 2,100 pounds per acre from the unterraced portion.

Prevention of Gullying

The foregoing results illustrate the effectiveness of terraces in controlling sheet erosion. Terraces are equally effective in controlling and preventing the development of gullies.

It has been observed that terracing generally improves fields for the operation of farm machinery by making the ground surface smoother. Gullied fields often must be divided into two or more parts because the gullies cannot be crossed safely with farm machinery. The land in such a gully and a strip on each side cannot be successfully farmed. Terracing such a field reclaims all of the land for cultivation and facilitates the use of farm machinery.

Figures 100 and 101 are views of a field on the soil-erosion experiment farm at Guthrie, Okla., before and after terracing. Before terracing the gullies were 3 to 8 feet deep and about 200 feet apart, and could not be crossed with teams or farm machinery, which necessitated the practice of farming the field in narrow strips between the gullies. The gullies were enlarging each year, were increasing in number, had lowered the ground-water table, and would soon have caused abandonment of the entire field because of loss of practically all the fertile topsoil. Small brush dams, as shown in figure 100, were built in the spring to assist in filling the gully with eroded soil, and the land was terraced in the fall. After the terracing, the gullies soon disappeared, and the field could be crossed anywhere with farm machinery.

Terraces are instrumental in building up and improving the fertility of the soil by retaining organic matter and applied fertilizer that other-

FIGURE 100.—A gully in which brush dams have been built to cause deposition of sediment carried by the water.

wise is soon carried off the field and deposited in drainage channels. A farmer in Mitchell County, Tex., reports that terracing a 40-acre field caused it to produce as much in 3 years as it formerly did in 6 years. Before the land was terraced it had never produced more than 10 bales of cotton per year. After the terracing it produced 58 bales in 3 years, which is practically as much as it previously yielded in 6 years.

Terraces conserve the rainfall and make it available for crops, thus effecting substantial increases in crop yields. Terraced rolling land on a farm in Borque County, Tex., yielded $37\frac{1}{2}$ bushels of corn per acre in 1929, when similar land unterraced, receiving the same treatment, yielded only $22\frac{1}{2}$ bushels per acre, and the difference in yield was attributed to the moisture retained by the terraces. The effect upon crop

FIGURE 101.—Cotton growing over the gully pictured in figure 100 after terracing.

yields of conserving moisture by terraces was demonstrated on a farm in San Miguel County, N.Mex. There terraced land yielded 700 pounds of beans per acre, as compared with 400 pounds per acre on unterraced land, and a corn crop on the terraced land was practically double that on the unterraced land.

Clean Cultivated Area Not Reduced

Terraces not only minimize erosion on cultivated lands, conserve moisture, and cause increased crop yields, but they do so without reducing the area that may be used for clean cultivated crops, such as corn and cotton, and without interfering appreciably with customary farming practices. The cultivation of fields in large units is economical of labor and of time, facilitates control of weeds and insects, and is conducive to low-cost crop production.

Bureau of Agricultural Engineering.

THINNING Plantations in Nebraska Forest Provides Fuel and Improves Stand

tions of the Nebraska sand hills and of supplying wood for the large number of farms and ranches in this rapidly developing part of the country. Up to June 30, 1933, 13,028 acres of coniferous trees had been successfully established on this forest. The first plantations were set out in 1903. During the earlier years of experimentation with species and methods the survivals were poor, and it was necessary to plant the trees close together in order to obtain a stand. From 1909 to 1911, inclusive, trees were planted 2 feet apart in rows about 6 feet apart. Weather conditions were favorable, and excellent survivals resulted. Consequently, these forest plantations became overcrowded, and by 1920 it was evident that they would have to be thinned.

Thinning a growing forest is as essential to maintaining proper growing conditions as thinning is to any other agricultural crop where spac-

The Nebraska National Forest was established in 1902 for the purpose of determining the practicability of growing forests on the rougher por-

FIGURE 102.—Planted in 1916, this jack pine plantation was thinned to 850 trees per acre in 1931. The material removed was used for fuel wood.

ing of plants is important in obtaining the maximum yield. A number of experimental thinning plots were established in 1920 and 1922 in stands of jack pine (*Pinus banksiana*) and Scotch pine (*P. sylvestris*), planted in 1910 and 1911 (fig. 102). Periodic growth measurements of the trees left showed that both the greatest average diameter and height increases were made on the plots with approximately 700 trees per acre.

With this information, extensive thinning was placed on a more scientific basis. In the winter of 1929-30 thinning was first undertaken on a large scale by six forest rangers. During that winter 44 acres were thinned and pruned, and 170 cords of wood were sold to local citizens, mostly for fuel. Some of the larger stems were used in fences and other general repair jobs.

The work of 1929-30 demonstrated that the local market was ready to absorb a great deal more wood than could be cut with ranger labor. Moreover, the area which needed immediate improvement cuttings

was too large to be taken care of in the limited available time of the forest personnel. Accordingly, during the winter of 1930-31, a method was devised of having the actual cutting and trimming work done by local citizens, and 7 acres of plantations were thinned and pruned.

Increased Demand for Fuel Wood

During 1931 the generally depressed economic conditions became more noticeable in this locality, and a greater demand developed for fuel wood from the forest. In many homes funds were not available to purchase fuel. Under national-forest regulations, the sale or free use of timber which should be removed to improve growth conditions is permitted. On this basis, free administrative-use permits are now issued to 37 applicants. The permits provided that the permittee must prune the lower branches to a height of 8 feet above the ground before any trees would be marked for cutting by the district ranger. All brush resulting from the cutting was scattered evenly over the area, except that cleared lanes were left between every fifth and sixth row of trees. In return for pruning the trees left on the area and for cutting such trees as the best silvicultural practice dictated, the permittee was given all material resulting from the thinning and pruning, except limbs that were less than 1 inch in diameter. During the last two winters, 102 permits have been issued to 30 different people, and 235 acres of plantations have been placed in better silvicultural condition. About 700 cords of wood were received by the men doing this work. The cost to the Government of thinning the plantations under this system amounted to \$5.66 an acre in 1933.

Through administrative free use, the thinning of the plantations now seems assured at very little additional investment. In many of the older plantations the struggle for existence between the trees has become serious, and some trees must be removed to maintain maximum growth. It is estimated that 1,000 acres are in need of thinning. Under the arrangement described, the farmers, in the vicinity of the forest and the forest alike are benefited. The forest receives needed thinning at little cost, and the farmer obtains a supply of fuel and general wood free, except for labor and transportation.

TIMBER from the Farm Woods has New Markets in the Pacific Northwest

Cutting back the virgin forests farther and farther from the centers of population in the Pacific Northwest has resulted in opening new markets

for farm timber for the manufacture of so-called minor products. A recent survey in Oregon and Washington shows that minor products have an annual sales value of \$16,500,000, while in volume they make up about 11 percent of the timber utilized each year. It is also evident that for raw material, manufacturers are depending more and more on second-growth stands. Almost without exception this means stands of rather limited area, such as are owned by individuals rather than by corporations.

In former days, when virgin timber was near at hand, the major portion of the demand for poles, piling, posts, fuel wood, pulpwood, mine timbers, ties, excelsior wood, and so on, was met by the large

operators. Practically the only outlet for timber from the farm woods was the farm itself. But times have changed. The increasing haul to market and the depletion of large timber tracts near farming communities have opened local markets of which the farm timberland owner can and is availing himself. The saw-log demand is still met principally by the large operator because of the necessity for special equipment to handle this product economically. But minor products are being handled more and more by the small producer. Some of these products require no special equipment for handling; others require but little. For all of them the specifications are rather simple and flexible. All can be easily marketed either directly to the consumer or to a nearby wholesaler. All are paid for in cash upon delivery. Most of them are best harvested during the season when other farm work is slack, thus providing a profitable use for labor, teams, and trucks. Couple these advantages with the fact that practically all of the minor forest products can be made satisfactorily from thinnings or material the cutting of which results in improvement rather than depletion of the stand, and the result is an easy and steadily profitable crop for the farm owner to handle.

It has been shown in every forested region of the country that properly executed thinnings which give each tree the ideal amount of growing space will speed up the tree growth. Under intensive management, it is possible to get about half again as much timber volume out of a stand in which thinnings are made at regular intervals as from an unthinned stand at maturity.

Among the products that thinnings will provide, fuel wood, pulp-wood, and fence posts find so ready a local market and require so little equipment for handling that they are worthy of detailed discussion.

Fuel Wood

Wood is the principal source of fuel in Oregon and Washington, not only in rural districts but in the towns and cities as well. The saw-mills and other wood-using industries provide hogged fuel and sawdust for domestic heating and commercial steam production. Although the shortage of suitable fuel-wood supplies and their greater cost have increased the use of coal, oil, gas, and electricity in the cities, still it is no unusual sight during the summer months to see residential streets in Portland lined with stacks of cordwood later to be sawed to stove lengths and stacked in cellars.

The species used for fuel wood in any section is determined primarily by the species available and only secondarily by the fuel value. Because of its abundance, for instance, Douglas fir furnishes over three quarters of the forest fuel wood consumed annually. Of this amount, nearly half comes from second-growth trees potentially valuable for saw timber. Most of the cordwood is cut by small, independent operators with an annual output of from 100 to 500 cords, but increasing amounts are being produced by farmers during the season when their labor cannot be used at other work.

The wood may be sold directly to the consumer, but near the cities most of the fuel-wood business is carried on through established fuel dealers. There seems to be no reason, however, why the farmer who is anxious to develop his fuel-wood market in nearby cities cannot do so. If a reputation for promptness and reliability is built up with a few customers, such a business will almost automatically increase.

Pulpwood

During the period from 1925 to 1930 the rated capacity of the pulp mills in the Pacific Northwest increased more than 100 percent, thus doubling the wood requirements (fig. 103). Until recently, pulpwood supplies were purchased largely in log form, but the last 5 years have shown a marked increase in the use of slab wood and other mill waste and the use of forest wood in cordwood form. About a quarter of a million cords of pulpwood valued at \$2,000,000 was used in 1930. Since then a larger proportion of the pulp-mill supplies has been made up of forest wood, primarily because the curtailed production of sawmills does not supply sufficient amounts of mill waste. Western hemlock furnishes over 50 percent of the forest pulpwood, the "balsam firs" about 25 percent, and the remaining quarter is made up of sitka spruce, black cottonwood, and Douglas fir.

FIGURE 103.—Pulpwood delivered on a sled to the contractor, who trucks it to the mill.

Fence Posts

Fence posts, both round and split, have long been staple returns from small woodlands. They are used on the farm, in nearby towns and cities, and by railroads and highways along right of ways. Many of them are sold directly by the producer; others are marketed through established dealers, especially in the larger cities. In 1930 over 4,000,000 posts were produced in Oregon and Washington. About half of these were marketed; the rest were cut by farmers for their own use. Western red cedar is the preferred species because of its durability. Where this species is not available, oak, juniper, larch, Douglas fir, and pine are used.

The Pacific Northwest farmer with a tract of woods on his farm has an asset worthy of development. Some study of the situation and inquiry in nearby centers will make clear the type of product which can be profitably marketed in his locality. Tall, straight trees which must be removed to provide growing space for others may be used for poles and piling. Some trees or portions of them may be suitable

for shingle bolts or veneer bolts; others may provide mine timbers or excelsior bolts. Extension agents and Forest Service employees are ready to give advice as to methods of improving the wood lot through thinning. Idle forest acres bring no income. They can be made to pay their way.

H. M. JOHNSON, *Forest Service.*

TOBACCO-DISEASE Control Necessitates a Wide Variety of Measures

Diseases, while always a serious problem in tobacco culture, have caused increasing losses in recent years. This has been due to an extensive spread of old troubles such as root knot and also to the appearance of diseases entirely new to this country, such as mildew, wildfire, and black shank. Omitting mention of relatively minor troubles,

FIGURE 104.—Effect of rotation on root knot. On the right is tobacco after 2 years of peanuts, with no evidence of root knot. The tobacco on the left followed 2 years of sweetpotatoes, and the plants show reduced growth and wilting of the leaves, both of which are evidence of severe root-knot injury.

our growers at present must contend with no less than four serious root diseases—root knot (*Heterodera radicicola*), black root rot (*Thielavia basicola*), brown root rot, and Granville wilt (*Bacterium solanacearum*). There are also five destructive leaf diseases—mildew or blue mold (*Peronospora* sp.), black fire (*Bact. angulatum*), wildfire (*Bact. tabacum*), drought spot, and mosaic.

Because losses from tobacco diseases vary so greatly with weather conditions, it is impossible to predict in advance the damage they will cause. In 1933 the mildew was widespread but only moderately destructive, while in 1932 it was the major factor in reducing the crop of flue-cured tobacco by some 300,000 acres. Troubles, such as mosaic, though widespread, are less conspicuous in their effects, because they do not kill the plants. The quality of a mosaic crop may be reduced as much as 60 percent, however.

The number and diverse nature of tobacco diseases necessarily require a wide variety of control measures. Among these, special crop rotations have been found most effective in combating root diseases that are soil-borne. Root knot, which is very destructive to tobacco,

FIGURE 105.—Control of mildew or blue-mold disease through temperature regulation: *A*, The plants were grown in a bed heated at night to maintain a temperature of 70° to 75° F. These plants remained healthy. *B*, The plants were grown in an adjacent bed without heat. All the foliage of these plants was either destroyed or severely injured at the time of the main disease attack, which occurred 11 days before this photograph was taken. It will be noticed that some leaves have been removed from the plants in *A*. This was necessary because of their proximity to the heating wires.

also attacks many other crops. It has been found that many crops considered to be root-knot resistant, however, cannot be used on diseased land in a tobacco rotation because they carry over abundant infection, even though not injured themselves (fig. 104). Out of many tested, a few nearly immune crops have been selected which can be used successfully on diseased land in a 3-year rotation with tobacco. One of the very best rotations was peanuts followed by oats the second year and tobacco the third. Similar work with Granville wilt and black root rot has established lists of immune crops that may be rotated with tobacco on lands affected by these diseases. For root-rot control the maintenance of a suitable soil reaction has also been found helpful.

Plant-Bed Sanitation Important

Many serious disease epidemics trace back to infections introduced while the plants are still in the bed, and these losses can largely be prevented by strict attention to plant-bed sanitation. (1) It is essential that the grower either select a healthy virgin-land location for the plant bed or else thoroughly steam-sterilize the old site. Refuse tobacco should not be used on the beds, nor should they be located near curing barns. (2) Since disease germs may remain alive on old boards or cloth, any old materials must be disinfected before being used. (3) Seed treatment should be practiced to destroy infection carried with the seed. (4) To avoid the chance of introducing mosaic, the grower should not work in his plants when he has been either sorting or chewing old leaf.

Nutrition as modified by fertilization and the practice of topping has been shown to have a marked effect on the susceptibility of tobacco to injury from leaf diseases, such as wildfire, black fire, and drought spot. The untopped plants are very resistant to these troubles. Low topping, especially in combination with high nitrogen fertilization, induced extreme susceptibility. Low nitrogen fertilization reduced leaf-spot injury, while low potash fertilization increased it.

The development of disease-resistant varieties gives great promise in the control of black root rot. Resistant selections have been secured of the burley, Havana, flue-cured, and Maryland types. Years of testing are required before these strains are released for general use, however, as it is essential that the resistance be combined with the exact leaf quality desired for the type.

Regulation of environment gives promise of solving the mildew problem, since experiments indicate that healthy plants can be produced by maintaining a night temperature above 70° F. during the critical period (fig. 105).

E. E. CLAYTON, *Bureau of Plant Industry.*

TREE Nursery Developed to Meet New Planting Program in Lake States

In the fall of 1933, 12,000,000 trees became available at the forest nursery at Rhinelander, Wis., for planting in the national forests of Wisconsin and the Upper Peninsula of Michigan. The nursery was established in 1931 to meet the need for stock demanded by the new planting program developed by the establishment in Wisconsin of units for the purchase of land for national-forest purposes and the rapidly increasing amount of land purchased in other units in the Lake States, together with the passage of the Knutson-Vandenberg Act.

Rhineland, located on a network of State highways and two railroads, was selected as the location of the new nursery after a thorough investigation of the various sites offered. The good transportation facilities afforded were given considerable weight in its selection.

The nursery was established on a 20-acre tract of suitable soil donated to the Federal Government by Oneida County. The tract was

FIGURE 106.—Nursery tract before development work was begun.

wild land, originally supporting a heavy growth of white pine but more recently supporting a young second growth of brush and inferior broad-leaf species (fig. 106). Before starting any work, a complete plan of the development was prepared. The plans included clearing and breaking the land and putting the soil in shape for production, road construction to make the area accessible and the nursery operation more economical, windbreak protection, and the location and con-

FIGURE 107.—General view of the nursery in October 1931, showing the progress of development work. Warehouse in left background.

struction of necessary improvements such as a warehouse, a pumping plant, fences, and an overhead water system. Since 2-year-old seedling stock is suitable for planting in the Lake States region, production at the nursery was planned on this basis. The usable seed-bed area was therefore divided into three blocks of approximately equal size. When the nursery is in full regular production, one block will be producing first-year seedlings, one block second-year seedlings, and the third block will be in green-manure crops for maintaining soil fertility.

Development work started on April 1, 1931, with the purpose of putting at least the first block in shape to be seeded in the fall. The brush was cut and the stumps blasted on approximately 17½ acres. A 15-30 tractor and a heavy 20-inch brush-breaking plow were used in the initial breaking of the soil. Block 1 was given intensive cultivation and the soil was in excellent condition for the seed beds, which were sown in October (fig. 107). Blocks 2 and 3 were sown to a cover crop of rye.

The water system, including a pump house, centrifugal pump, 1,925 feet of 3-inch distribution main and overhead lines operated by hydraulic motors, has been installed complete. The pumping unit consists of a 35-horsepower gasoline motor, connected to a centrifugal pump capable of delivering 200 gallons of water per minute at a pressure of 45 pounds. Water from a lake passes by gravity through a sand and gravel filter to a reservoir, from which it is pumped. The system is designed to deliver a maximum of one fourth inch of water over an entire block daily. During periods of normal precipitation, less water will be used.

Capacity Production in First Year

The work planned for the first year was fully accomplished, and the nursery was placed on a capacity production during the first year of its development. The major improvements accomplished during the year include the construction of 0.6 mile of road, the fencing of the entire area, clearing and breaking the usable area, completing the water system for the first two blocks, building the warehouse and two latrines, planting a windbreak around the exterior, and hedges on interior block lines, the laying of 133,000 square feet of hardware cloth for protecting seed beds from birds and rodents, and making 27,000 feet board measure of seed-bed frames and stakes.

Additional improvements consisted of setting up an office and laboratory for the nursery superintendent in charge and a seed extractory for the extraction of seeds from locally collected cones, and installing the overhead water system for block 3.

By the fall of 1933 the number of trees available for planting exceeded by 2,000,000 the production originally predicted. Block 2 was partially seeded in the fall of 1932 for the production of 1934 planting stock. Coincident with the authorization of the President's Emergency Conservation Camps, it became apparent that a much greater amount of planting stock would be needed to assure a maximum reforested area. The remainder of block 2 and all of block 3 were seeded, and there are now in this nursery 25,000,000 seedlings which will be of suitable size for planting by the fall of 1934.

Experience in the region indicates that 2-year-old seedlings can be produced at a cost of less than \$1 per thousand. Planting these trees will cost approximately \$2 to \$3 per acre additional, depending on the character of the planting site. Approximately 75 percent of the total cost of producing the trees and planting them in the field is spent for labor.

H. BASIL WALES, *Forest Service.*

TRUCK-CROPS Index Constructed With 13 Products Included

The new index of prices to producers of commercial truck crops for shipment to market is an attempt to supply, in part at least, a long-recognized need of the expanding vegetable and truck-crop industry.¹⁰ The seasonal nature of most of these crops with their intermittent appearance on the market and their sudden price fluctuations have necessitated the use of a different type of index number from that used for farm products in general. Like every type of index number, it has inherent limitations. The scope of the index is limited by the inadequacy of price data. It is presented at this time with the hope that even in its preliminary form it may serve a useful purpose and that helpful suggestions and criticisms may be forthcoming.¹¹

Contribution of Truck Crops to Farmers' Income

The 1924-29 average farm value of 13 commercial truck crops for market (those included in the index) was \$186,000,000, which is about equivalent to 61 percent of the total cash farm income from all truck

FIGURE 108.—Index of prices of truck crops to producers, adjusted for seasonal variation, since January 1924. Prices of fresh vegetables and other truck crops fluctuate widely because of their highly perishable nature. In addition to the irregular price fluctuations here shown, truck-crop prices undergo a typical seasonal variation, from high prices in winter to low prices in summer. This normal and well-known seasonal variation has been eliminated in the computation of this index of truck-crop prices to producers.

crops of \$306,000,000. Farm value exceeds cash farm income by the value of agricultural products used on the farm, but for producers of commercial truck crops this difference is small, for only a small proportion of these are consumed by the farm family. In addition to the average farm value of \$186,000,000 from the for-market portion of these 13 truck crops, the value of tomatoes, green peas, asparagus, snap beans, spinach, and cabbage for manufacture averaged \$41,305,000 from 1924 to 1929. Truck crops contributed 3.1 percent of the average cash income to farmers from 1924 to 1929, potatoes contributed 2.8 percent and sweetpotatoes 0.7 percent.

¹⁰ The term "truck crops" rather than "fresh vegetables" is used here in order to meet certain objections to classifying tomatoes, cantaloups, watermelons, and cucumbers as vegetables. Commercial truck crops for shipment include vegetables and other truck crops grown primarily for shipment by rail, boat, or motor truck to markets more or less distant from the point of production. This commercial classification excludes strictly market-garden production, production on farms for home use and local sale, and quantities utilized by canning or packing establishments.

¹¹ A complete report, including tables, is available in mimeographed form. Current index numbers are published each month in the regular monthly report of the Crop Reporting Board on Average Prices Received by Farmers for Farm Products.

Commodities Included

Thirteen commodities are included in the index, the number varying each month from 5 in January, February, September, and November to 11 in June. These commodities in decreasing order of their average importance in the index are as follows: Tomatoes, lettuce, cantaloups, onions, cabbage, celery, snap beans, watermelons, asparagus, green peas, cucumbers, spinach, and carrots. Tomatoes, for example, although given the largest weight—on an average—are included in the index only from April through October.

Changes in Truck-Crop Prices

Pronounced price fluctuations are characteristic of truck crops largely because of their highly perishable nature and the rapidity of changes in supply, especially within a local market or supply area. A night frost may result in an overnight increase in cabbage or lettuce prices of as much as 1,000 percent. Within the time required for such a high short-time supply price to attract an influx of supplies from more distant areas, which may be but a few days, the price may recede to below its former level.

With a recognition of these probabilities, let us look at the accompanying chart on the index of truck-crop prices (fig. 108). The index problem resolves itself into two questions: (1) Whether sufficient facts are available, and (2) whether the index truly represents the facts. The first question has already been discussed, and the desirability of enlarging the scope of the index—which should increase its stability—as more and better price data become available, has been recognized. Most of the major price fluctuations occur from November to March, which is the slack season in the number and supply of fresh vegetables coming to market. When, as, and if prices are obtained for storage stocks of such vegetables as onions and cabbage, these may be incorporated in the index, which would reduce the instability during the winter months.

An examination of the reported price changes for the individual crops seems to justify an affirmative answer to the second question, as to whether the index does a good job of its assigned task.

An analysis of the factors contributing to the rise in the index from August to September 1933 may help to emphasize the nature and operations of the index. Several factors contributed to this rise in the index, only one of which was an actual increase in price. Tomato prices more than doubled, and at the same time the weight of tomatoes in the index was nearly trebled. Watermelon prices were unusually low in July and August and exerted a downward pull on the index until September, when the watermelon season is practically over. The sharp increase in tomato prices from August to September was contrary to the usual seasonal decline. Lettuce and cabbage prices declined some from August to September but less than usual, thus tending to raise the index which is adjusted for normal seasonal variations.

Weights

The weight for each commodity is based on the estimated quantity marketed by months for the 6-year base period, 1924–29. In the determination of these monthly weights the percentage distribution of carlot shipments was first computed for each commodity as an indication

of the relative volume of marketings from month to month. If motor-truck shipments had been available to add to the car-lot shipments, the percentage distribution of marketings would have been somewhat different. Motor-truck shipments are relatively more important in the summer and early fall months when areas near large northern cities are important sources of supply. However, motor-truck shipments generally, and perhaps more so in the summer, were relatively much less important compared with car-lot shipments in the period 1924-29 than in the years since 1929.

The next step in computing the weights consisted of multiplying the monthly shipment percentages by the average annual production of these "commercial truck crops for shipment" from 1924-29. These estimates of the actual quantities marketed by months for each crop were used as fixed quantity weights for the corresponding month of each year. The average quantities marketed in January from 1924-29 for example, were multiplied by the average of January prices for the same 6 years and the resulting base value made equal to 100 percent. For any one January, the index would be the percent which the value for that particular month is of the January base-period value.

Effects of the System of Weighing

The use of fixed quantity weights in constructing index numbers from continuous series is relatively simple, and, if quantities do not vary greatly from their relation to one another in the base period, an index of this type is often the most suitable measure of composite price changes. On the other hand, actual or given quantity weights may be multiplied by the price for each month or other period. An index computed from quantities and prices, both of which are continually changing, is essentially an index of income. Higher prices tend to be offset by smaller quantities and vice versa.

This index of truck-crop prices has both fixed and variable weights—paradoxical though it may seem. The weights are fixed for the corresponding month of every year, but they vary from month to month throughout each year. This makes possible two sets of comparisons: (1) A strict year-to-year price comparison between corresponding months for an identical "basket" of commodities and (2) a price comparison between successive months, with the normal (1924-29) seasonal variation eliminated, for a "basket" of commodities which varies in size and in composition from month to month.

ARTHUR G. PETERSON,
Bureau of Agricultural Economics.

VIRGIN Animals Secrete Milk After Injections of Pituitary Hormone

Until the most recent years, scientists and laymen alike believed that full development of the mammary gland and the actual secretion of milk could be brought about only by the normal processes occurring during pregnancy. In the last 2 or 3 years, however, an earnest experimental attack has been made by American (Corner, Turner, Asdell) and European (Grüter and Stricker) investigators in an effort to determine just what factors cause the growth of the mammary gland and, finally, how milk secretion is brought about. Careful investigation has shown that

pregnancy is not necessary for full development of the mammary gland and milk secretion, but that by injection of the proper materials virgin animals—male as well as female—can be made to elaborate and secrete milk.

What the exact mechanism of the entire processes of mammary-gland growth and milk secretion actually is, research workers are not wholly sure. Most investigators are familiar with the appearance of a well-developed follicle on the surface of the ovary at the time of oestrus, and are equally well-acquainted with the corpus luteum ("yellow body") that develops when the ovum is shed. It appears from the work of several investigators, mainly Turner and his collaborators at the University of Missouri, that the hormone theelin (presumably produced by the developing follicles) is responsible for the extension of the duct system, and that theelin acts together with the corpus-luteum hormone to stimulate complete mammary growth. But these two hormones alone will not cause milk to be secreted. It is here that the stimulus produced by the anterior lobe of the pituitary gland (a small gland about the size of a hazelnut, lying at the base of the brain) comes into play.

Experiments carried out during the past year at the Physiological Laboratory, Bureau of Dairy Industry, add further support to the theory that the anterior lobe of the pituitary gland elaborates a substance, i.e., a hormone, which initiates the actual secretion of milk. It is not known for certain the extent to which the mammary gland system must be developed by theelin and the hormone of the corpus luteum before secretion can take place in the mammary gland; more work is needed in order to settle this point. Accumulating evidence tends to show, moreover, that the hormone which brings about secretion of milk is not identical to those substances, also secreted by the anterior pituitary, that promote growth, stimulate the thyroid and adrenal glands and are necessary for the normal development and activity of the male and female sex organs.

Experiments with Cows and Goats

In most of the experiments in other laboratories small mammals, such as the rat, guinea pig, and rabbit, have been used in the study of the factors responsible for the control and stimulation of milk secretion. It was thought that some studies should be carried out on animals whose primary function among civilized peoples is the production of milk for human consumption. Experiments have therefore been made on virgin cows and virgin milk goats. With these species it is possible to determine in a quantitative manner the lactation response to the injected hormones. Then, too, there are available for comparison the records of milk yields from normal lactating animals.

Several virgin milk goats were selected and injected over a period of 6 days with 15 cubic centimeters of an extract of the anterior pituitary. By the third day a striking change in the appearance of the udder was evident and on the sixth day the udders of all the injected animals were so swollen with milk that it was thought wise to institute milking. On the first milking the goats produced from 1.8 to 4 pounds of milk. Thereafter the goats were milked twice daily, their level of production agreeing quite well with the average of the normal goat lactating after pregnancy. Also, injection of this same extract into a mature goat during her dry period introduced a new lactation without parturition.

This particular goat secreted about 7 pounds of milk daily for some time after the injection had been made.

Similar results were obtained by the injection of extracts of the anterior pituitary gland into a virgin dairy heifer. In this instance the Bureau investigators were able to maintain the average of 15 to 18 pounds of milk daily from a virgin Jersey heifer for several months after they had ceased giving the injections. Figure 109 illustrates the appearance of the mammary gland of a virgin goat prior to and 6 days after the first injection of the anterior pituitary extract. From this illustration it may readily be seen that there has been effected a considerable increase in size of the gland, due in part to the accumulated milk that was secreted under the influence of the injected lactation-stimulating hormone.

Hormone Stimulates Mammary Gland

For some time the Bureau investigators were under the impression that their preparations of this lactation-stimulating hormone from the

FIGURE 109.—Showing the mammary gland of a virgin goat (A) prior to and (B) 6 days after the first injection of anterior pituitary extract.

anterior pituitary might be acting, in the case of an animal whose own pituitary was intact, only as a stimulant to the animal's own pituitary to secrete additional quantities of her own hormone. Recent experiments indicate, however, that such is not the case. The point was settled by experimental surgical removal of a female dog's pituitary gland. The dog recovered from the operation and in 24 hours appeared normal in every respect. Subsequent injection of a fairly pure preparation of the hormone into this same dog caused copious milk secretion from hitherto nonlactating mammary glands 18 hours after the first injection. As a result of this test, the Bureau investigators feel that the material they are injecting into normal animals is stimulating the mammary gland directly and not by way of the animal's own pituitary gland.

Certain of the Bureau's experimental cows were thought to have received an inheritance for levels of high production. Nevertheless, their producing performances were disappointing. It was thought that perhaps one of the reasons for this low production might be the secretion in insufficient amounts of the lactation-stimulating principle by their own anterior pituitary glands. Therefore, the Bureau investigators injected extracts of the anterior pituitary into these low-producing cows. They found that in some cases production increased 25 to 50 percent above the levels maintained immediately before the injections were given. It should be emphasized, however, that these higher levels of production were not maintained after the injections were discontinued.

Although the Bureau investigators are aware that failure of the anterior pituitary to secrete proper amounts of its lactation-stimulating hormone in cases of poor milk producers is not the only cause for failure of higher production, they do believe that the anterior pituitary is one of the more important links in the process of mammary-gland growth and milk secretion. Further work is necessary to determine the relative importance of this and other glands of internal secretion in milk production.

Possibilities in Human Medicine

What the Bureau investigators are learning of the role of the anterior pituitary in milk secretion in dairy cattle may be of primary importance to certain problems in clinical medicine. It is well known that a large percentage of mothers fail to secrete enough milk immediately after the birth of a child to provide complete nourishment for it. When hormone preparations of the lactation-stimulating principle are pure enough to warrant their application to this problem in medicine, it is possible that injection of them may bring about a more abundant secretion of milk in these cases.

TUBERCULOSIS of Poultry is Being Greatly Reduced by Disposing of Old Hens

The disposal of all hens in a flock after they have reached the age of 18 months is meeting with the enthusiastic approval of many flock owners in the Middle Western States. This seemingly drastic procedure, commonly termed "giving the old hen a ride", was designed as a means of eradicating avian tuberculosis, which is the cause of heavy losses on many farms. The effectiveness of the plan centers on the fact that fowls seldom become spreaders of tuberculosis until they are at least a year old. Thus the elimination of hens that have reached the age of 18 months, or after they have finished their first laying year, prevents the disease from getting a foothold, avoids losses through decreased egg production and the death of hens, and permits the maximum production of fall and winter eggs that bring the best prices. Old roosters should also be marketed.

When veterinarians engaged in bovine-tuberculosis eradication made a survey of poultry flocks during 1927 they found that avian tuberculosis was a serious menace to poultry in more than 500 counties in the Central and North Central States. In some areas as many as 15 per-

cent of the swine were also affected with the same type of the disease. In most cases where infected swine were found they had been allowed to run with tuberculous poultry.

The eradication of tuberculosis from poultry flocks was begun in a cooperative way in 1931, when the Federal appropriation for tuberculosis-eradication work was increased to include work with poultry as well as cattle. Representatives of practically all branches of the poultry industry met with State and county livestock officials to formulate plans for cooperating in this work. These representatives agreed on a plan for conducting work in restricted areas where State or Federal veterinarians could visit each flock in a county and explain to the owner how to detect the disease by the appearance of the live birds and by post-mortem examination. These inspectors were prepared to apply the tuberculin test to exhibition or high-production flocks in which the value of the fowls was too great to justify making post-mortem examinations.

Fowls Inspected on 2,900 Farms

In counties where the intensive plan has been conducted the veterinarians engaged in this work inspected approximately 4,253,000 fowls on 29,000 farms during the fiscal year ended June 30, 1933. In some counties these workers have completed their second survey of the flocks in order to determine the effectiveness of the work. In one county where more than 600 flocks were inspected, the second survey showed that 92 percent of the flock owners were making substantial progress in eradicating avian tuberculosis. The townships in which most improvement occurred were those in which bovine tuberculosis had been successfully eradicated. In another county the inspector applied the tuberculin test to 42 hens in a flock known to have been infected but from which all the old hens had been eliminated. There were only 2 reactors. The owner of another infected flock in the same county had relied only on moderate culling, in connection with egg production, to eradicate the infection. The application of the tuberculin test to 44 of these hens showed 9 reactors, or more than four times as much infection remaining on the premises. Infected flocks from which the old hens have not been removed often show as high as 50 percent of reactors to the tuberculin test.

In many States where no intensive campaign is in progress the flocks may be inspected by veterinarians who are conducting bovine-tuberculosis eradication. Work of this kind is being carried on in 21 States and last year served nearly 170,000 flock owners having approximately 16,000,000 fowls. This plan provides merely for pointing out symptoms of tuberculosis, offering to make post-mortem examinations of suspected birds, and giving suggestions for eradicating the infection from the premises. In many cases the flock owner does not realize that the disease is getting a foothold until he sees the actual lesions of the disease in one of his hens on post-mortem examination.

If the symptoms in a flock are pronounced the owner is advised to send all his birds to market and start with a new flock on clean ground. Sanitation is important since the tubercle bacilli may live in protected places for a long time. All buildings used by infected birds should be thoroughly cleaned and disinfected in order to protect healthy stock. The disposal of all hens after they have reached the age of 18 months is a precaution that should be followed on farms where there is any pos-

sibility of fowls picking up the infection. Runways and pens used by infected flocks should be plowed up and planted to a green crop whenever possible.

Common Symptoms of Avian Tuberculosis

Poultry raisers should acquaint themselves with the symptoms and post-mortem appearance of tuberculosis in poultry so that they may detect the disease should it become established in their flock. The more common symptoms are found in birds over 1 year of age, as tuberculosis requires a number of months to develop sufficiently to interfere to any great extent with the function of the body. One of the first symptoms to be noticed is lameness in one or both legs. Other common symptoms are ravenous appetite, extreme weakness, and gradual emaciation, which becomes very noticeable in the breast. A mature hen may continue to lose weight until she weighs only about 1 pound. As the disease advances, the comb, wattles, skin of the head, and membranes of the mouth become pale. The bird weakens and gradually develops a tottering gait. Usually only a few birds in a flock die at a time, and in most cases these are the older birds.

FIGURE 110.—Veterinarian of the Bureau of Animal Industry demonstrating to a flock owner the presence of tuberculosis in a fowl.

On post-mortem examination a fowl extensively affected with avian tuberculosis will show numerous tubercles in the liver, spleen, and walls of the intestines (fig. 110). The tubercles may be white or yellow, and vary in size from that of a pin point to that of a walnut. The liver may be many times enlarged, occupying about half the abdominal cavity. The spleen also may be greatly enlarged.

That there is great need for energetic efforts to be continued in the eradication of avian tuberculosis is shown also in reports covering post-mortem examinations of market poultry in various sections of the Middle Western States, where shipments of fowls are found with as high as

15 percent of infection. Establishments engaged in canning poultry meat often refuse to buy fowls from districts having even a moderate degree of infection because of the losses resulting from affected parts, which must be destroyed.

ELMER LASH, *Bureau of Animal Industry.*

VEGETABLE-DESCRIPTION The Yearbook of Agriculture Work Progresses; First Reports Now Available for 1932 contained a brief outline and progress report upon the Department's vegetable variety standardization and description project. Nearly half of the State agricultural experiment stations, widely distributed over the country, have cooperated with the Department in studying a total of 78 of the most important varieties of tomatoes, cabbage, peas, carrots, beets, spinach, and onions. Many hundreds of strains and stocks have been grown and carefully studied in about 25 different locations in informal collaboration with representatives of the seed and vegetable industries. The first completed reports on this large, long-time project are now available at small cost. These publications are thoroughly illustrated, many of the illustrations being in natural color. The publications now available are as follows:

Miscellaneous Publication 160, Descriptions of Types of Principal American Varieties of Tomatoes. Price 35 cents.

Miscellaneous Publication 169, Descriptions of Types of Principal American Varieties of Cabbage. Price 40 cents.

Miscellaneous Publication 170, Descriptions of Types of Principal American Varieties of Peas. Price 45 cents.

Descriptions and illustrations of the most desirable type of each variety are presented, together with other descriptions and illustrations of unavoidable deviations from the standard type that may be obtained in different parts of the United States. It is thus recognized that a certain variety may not—indeed usually does not—exhibit the same appearance under all the conditions under which it can be successfully grown. This is an especially important feature of the work, since it represents the first attempt to prepare for vegetable varieties descriptions that can be used with confidence on a Nation-wide basis.

Orders and remittance for these publications should be sent to the Superintendent of Documents, Government Printing Office, Washington, D.C.

VICTOR R. BOSWELL, *Bureau of Plant Industry.*

VITAMIN Standards of Vitamins have assumed such an International Conference important role in nutrition that in Being Adopted in U.S. recent years particular attention has been devoted to their quantitative determination. Physical and chemical methods are now being developed which may prove satisfactory for the determination of some of the vitamins in particular products, but for the present we must rely on biological assays, that is, determination of the vitamin content of a product by the use of experimental animals.

Differences in the methods of biological assay developed by various investigators have led to a great deal of confusion in expressing the vitamin content of our foods. This has hampered progress in research and made control problems difficult. When a poultryman, for example, attempts to compare the relative merits of cod-liver oils from different sources, he finds that the vitamin D content of the oil is expressed in three different units whose comparative values are understood by only a few scientists. The physician is confronted with the same vexatious situation in choosing a vitamin-D-containing product in the treatment of rickets.

In June 1931 there was held in London an international conference, sponsored by the League of Nations, to consider standards for vitamins with the hope that the same designation for vitamin content would be adopted universally. This country was represented by two official delegates. At this conference standards for vitamins A, B, C, and D were adopted, and a unit of each of these vitamins was defined. The standard for vitamin A is a specified preparation of carotene, and one unit is defined as the vitamin A activity of one millionth of a gram of this preparation.

The standard for vitamin B is a specified preparation from rice polishings, and a unit is the vitamin B activity of one hundredth of a gram. The standard for vitamin C is lemon juice, and a unit is the vitamin C activity of 0.1 cubic centimeter. The standard for vitamin D is a specified preparation of irradiated ergosterol; the unit is the vitamin D activity of one thousandth of a gram of this preparation. (For the benefit of those who are not familiar with the terms gram and cubic centimeter, it may be stated that there are approximately 454 grams or cubic centimeters in 1 pound of water.) When used in parallel feeding experiments, these standards permit a more accurate evaluation of the vitamin content of a product, and they also permit investigators working in different laboratories to express vitamin content in the same terms.

Suitable quantities of the standard for vitamins A, B, and D have been sent to a central distributing agency in each country. The Protein and Nutrition Division of the Bureau of Chemistry and Soils acts as a distributor in this country. It is, however, only a matter of courtesy to the League of Nations, through whose generosity the standards are made available to us free of charge, to put definite restrictions on the distribution of these preparations.

Through the cooperation and aid of the board of trustees of the United States Pharmacopœia, there is now also available through the chairman of the United States Pharmacopœia revision committee a so-called reference cod-liver oil, whose vitamins A and D content in terms of international units has been carefully established, and standards for vitamins A, B, C, and D are available in sufficient quantities for every legitimate need.

International Standards in Great Demand

Investigators and manufacturers in the United States have shown a desire to adopt the international units, and the standards have been in great demand. The relationships between the international units and other units now in use have been fairly accurately established, and early adoption of the international units may be looked for. With the universal adoption of the international vitamin units, cod-liver oil

manufactured in Norway, Newfoundland, and the United States will have their vitamin D content designated in the same units, and the manufacturer of a medicinal or food product will no longer have to label its vitamin D content in two different units in order to make clear the quality of his product.

While the present standards have, in general, proved satisfactory, the rapid developments in elucidating the chemical nature of vitamins during the past 2 years have made possible further improvements. A second international conference is now being planned for June 1934, and consideration has already been given to the adoption of ascorbic acid as a standard for vitamin C. Pure ascorbic acid has the physiological properties of vitamin C, and it can be prepared in sufficient quantities and with a satisfactory degree of purity to serve as a standard for biological assays. Other changes may be made from time to time, but from the standpoint of practical utilization of the vitamins it will probably be many years before so notable an advance will occur again as the adoption of the international standards in 1931.

E. M. NELSON, *Bureau of Chemistry and Soils.*

WHEAT Leaf Rust Lowers Milling and Baking Qualities

Leaf rust of wheat, in contrast with stem rust, seldom causes a complete crop failure even in severely infected fields. It does, however, materially affect the

quality of the grain and of course reduces the yield somewhat. Also,

FIGURE 111.—Effect of leaf rust on the quality of Fulhard wheat kernels: A, Kernels from rusted plants, showing high percentage of yellow berry; B, kernels from nearly rust-free plants, showing a low percentage of yellow berry.

strange as it may seem, the kernels are not shrunk as they are with stem rust, being usually fairly plump and on casual inspection not greatly different from those from nonrusted fields. The difference is mainly in the protein content of the grain, that from rusted fields usually containing the lesser amount.

While the effects of leaf rust in general

are much less serious than those of stem rust, leaf rust occurs more frequently and affects a larger territory. It is often present in serious amounts from the extreme southern part of the United States to the Canadian border. Hence, the effect of leaf rust on the quality of the grain is a matter of considerable importance.

Experiments have been conducted cooperatively by this Department with the botany and chemistry departments of the Purdue University Agricultural Experiment Station that show the effect of leaf rust on wheat quality. By dusting certain small areas of wheat with sulphur it is possible almost entirely to prevent leaf rust from developing on

the plants, while similar nearby areas become severely rusted. When diseases other than leaf rust are absent, comparisons of the grain from such rusted and nonrusted areas show the effect of leaf rust on the quality of the grain (fig. 111). The grain from leaf-rusted plants appears lighter in color, contains many more yellow-berry kernels, and is lower in protein content than that from nonrusted plants. This may be a serious defect, especially in those areas that normally secure a premium for high-protein wheat. The yield of grain is also reduced materially though not so much as might be expected.

Other Causes of Low-Protein Grain

Wheat leaf rust is not the only cause of yellow-berry low-protein grain. Certain soil fertility and weather conditions also are known to produce this result. However, it may well be that a leaf-rust epidemic, acting either alone or with these other factors, has frequently been largely responsible for the poor quality of wheats harvested in areas that usually produce good hard wheats.

Leaf rust of wheat, in contrast to its relative, stem rust, lives through the entire year on the wheat plant. Therefore, no eradication plan will remove the source of leaf-rust infection. The sulphur dusting that will control leaf rust is too costly to be applied. Thus no means of practical control of this disease is available except the breeding of desirable wheat varieties that do not take the leaf rust. Such breeding work is in progress and gives promise of eliminating the disease as a factor in lowering the yield and the bread-making quality of wheats.

R. M. CALDWELL, *Bureau of Plant Industry.*

WHEAT-Production-Control Program Wins Farmer Support

On June 20, 1933, the Secretary of Agriculture announced that under the new Agricultural Adjustment Act adjustment payments would be made to the wheat farmers of the United States if they would sign contracts with the Agricultural Adjustment Administration, agreeing to join with their neighbors in reducing the Nation's total production of wheat so that it would again pay them to grow wheat. Upon the proclamation of the Secretary and the decision of the administrators of the Agricultural Adjustment Administration has been built wheat-production-control machinery extending into 1,700 counties in 40 of the States and involving half of all of the farms in the United States which in recent years have been producing wheat.

The task of getting the wheat program under way was colossal. It meant the blazing of new trails, the formulation of new policies, and the setting up of new machinery for giving actual effect to the production-control program.

One of the most important steps in the wheat program was to plan and get under way a far-reaching educational campaign. This campaign was designed to reach every wheat grower in the United States whom it was possible to reach. It was carried on through the Federal and State cooperative agricultural extension service. The main purpose of it was to carry to farmers the latest and best information available on the production, market movement, and consumption of wheat,

and on the economic position of the wheat production of the United States in national and international trade. Throughout the educational campaign the fact was emphasized that the entire program under the Agricultural Adjustment Act was a voluntary program, sponsored and promoted by the Federal Government in order that the producers themselves might control and stabilize their own wheat-production operations.

The Educational Campaign

The educational campaign was carried on through meetings of farmers, informative articles in the press, talks and discussions over the radio, personal contact with the growers, circular letters, and every other available and feasible medium. The general direction of the educational campaign was placed by the Secretary of Agriculture in the hands of the cooperative Federal and State Extension Service, and in the local wheat-producing communities it was directed by the county agricultural extension agents and by the emergency agricultural agents.

Meetings of extension people and wheat producers were held in every community in the main wheat-producing States. At these meetings the people in charge of the campaign presented the latest and best information available on the wheat situation, both domestic and world; on the change in the position of the United States from that of debtor to that of creditor in international affairs; on the restrictions placed upon international trade by the various nations after the World War, with resultant shrinkage of the former export outlets for our goods of all kinds, including wheat, and on the general struggle of the nations of the world to find export markets for their products. Everywhere it was emphasized that it had become absolutely necessary for the farmers of the United States to reduce their total production of wheat to the point where a market could be found for the supply produced, and that they then must maintain production on a level where it would bear a sound relationship with effective demand.

The attention which was given to the educational part of the program was not confined to the economic situation of wheat alone. The Agricultural Adjustment Administration of course recognized the interrelation of all of our agricultural commodities in the national and the world economy, and it therefore endeavored in the wheat campaign to lay a foundation for all of the commodity programs which were to follow, so that all farmers would have a broad understanding of the principles involved.

The results of the educational campaign fully justified the emphasis which was placed upon it. About 750,000 wheat producers of the United States, including both landlords and tenants, gave their hearty support to the principle of production control. That number of individual contract signers, who signed a total of about half a million contracts, associated themselves together in county or district wheat-production-control associations, covering approximately 1,700, or all, of the principal wheat-producing counties of the United States.

More than 30,000 workers assisted the wheat producers in preparing and filling out their applications for adjustment contracts and their contracts. Nearly 5,000 members of the allotment committees of the county and district associations calculated the individual farmers' allotments, and certified to the applications and contracts.

Control Associations to Continue

The wheat-production-control associations are continuing organizations; they will continue to exist as active organizations of the wheat producers, at least for as long as the present contracts extend, for the reason that adjustment payments can be made only upon certification by the local allotment committees, the members of which are elected by the members of the association.

In the formulation of the wheat program certain principles were accepted as fundamental and therefore essential. Some of these were:

- (1) The total volume of wheat production in the United States must be reduced to and be kept within effective demand.
- (2) The administration of the wheat program must be left with the farmers themselves just as far as possible.
- (3) The farmers who cooperate in the program must, by reason of their cooperating, be given advantage which noncooperators would not have.
- (4) The program should be based upon the cooperator's past production and acreage.
- (5) Production control should be accomplished through acreage control.
- (6) The program should have such flexibility as to enable it to meet any changes in conditions which might occur from time to time, and also it should enable the United States to conform to any commitments which it might make with other nations of the world for the regulation of wheat production and the exportation of wheat.
- (7) The purchasing power of the United States wheat grower's wheat must be restored to where it was in a pre-war period.
- (8) The increase in the return to the producer for his wheat should be borne by the consumer of the wheat and not through general taxation.
- (9) The consumer must be protected from undue increases in prices in restoring purchasing power to the farmers.

In accordance with these principles, the wheat program, which was drafted by the Wheat Section of the Agricultural Adjustment Administration and approved by the Secretary of Agriculture and the administrators of the act, contained the following main provisions:

- (1) Production-adjustment payments should be made to cooperating producers for each of the crop years 1933, 1934, and 1935.
- (2) The basis of payment should be the producer's actual average production in a base period, and his acreage reduction should be based upon the actual acreage which he had in wheat in the same base period.
- (3) Payments should be made according to each producer's share of the total amount of wheat which is domestically consumed in the United States and upon which the processing tax would be paid, such share to be called the producer's farm allotment.
- (4) The percentage of acreage reduction should be determined by the Secretary of Agriculture within the limit of 20 percent of the producer's base acreage.
- (5) The funds necessary for making the adjustment payment to the producers should be provided by a processing tax on the wheat processed for human food.
- (6) The consumer should be protected by the requirement that each producer cooperating in the program would be required to sow a sufficient acreage of wheat to produce his allotted proportion of the total amount of wheat domestically consumed.
- (7) The local administration of the wheat program should be carried on by and through county and district wheat-production-control associations, the membership of which would consist of the cooperating producers and the officers of which would be elected by the members themselves.

Eighty Percent of Acreage Covered

The sign-up of wheat-production-adjustment contracts covers approximately 80 percent of the total wheat acreage of the United States. The proportion of the total acreage which was signed up by the comparatively large producers was greater than it was first thought would

be the case; there was a tendency for the smaller producers who had been growing wheat for only local and home consumption and livestock feed to remain outside of the program. As the anticipated sign-up of a total of about 80 percent of the Nation's wheat acreage was accomplished by the signing up of only about half of the farmers who ordinarily raised wheat, the amount of local organization, the cost of administration, and administration problems were not as great as they might otherwise have been.

The funds for making the adjustment payments to the wheat producers are derived from a tax on the volume of wheat processed for human consumption. At the inception of the wheat program the processing tax was placed at 30 cents per bushel. The adjustment payments to the producers were placed at the same amount per bushel on the basis of each producer's production allotment, less a small percentage for setting up a reserve fund for taking care of whatever losses might be involved in the exportation of a certain amount of our existing burdensome surplus.

In January, when this was written, it was estimated that the total amount of the adjustment payments to be paid to producers in the first year of operation of the wheat program would be about \$100,000,000, about \$70,000,000 of which would be represented by the initial payments on the contracts.

In the summer of 1933 proposals for the control of wheat production on a world basis were laid before the World Economic Conference which was held in London, England, during the summer and which was commonly referred to as the London Economic Conference. At this conference many of the countries of the world were represented, and the world wheat situation was one of the important subjects for consideration. The conference recognized the fact that the constantly growing world wheat surplus had been adversely affecting world trade to an extent which seriously interfered with economic recovery in the principal wheat-producing nations, especially those which had been exporting large quantities of wheat. The conference laid down a general program having as its object the control of production and the reduction and prevention of burdensome surpluses. The conference reached agreement on wheat, and under the agreement the United States was allotted an export quota of 47,000,000 bushels for the year 1933-34 and 90,000,000 for the year 1934-35. The base period which the conference adopted as the basis for the world wheat-production-control program was the years 1930-31, 1931-32, and 1932-33. This base covered a period ending 1 year later than the base which had been adopted by the Agricultural Adjustment Administration for our own wheat program. When the agreement was reached the United States was the only one of the nations which had the necessary machinery in existence for making wheat-production control possible. This control was provided for by our recently enacted Agricultural Adjustment Act.

Effect of Tax on Consumption is Vital

Inasmuch as the funds for making the adjustment payments to the wheat farmers are derived from the tax on processed wheat, the effect of the tax on the domestic consumption of wheat is of vital importance to the success of the plan. Under the Agricultural Adjustment Act, wheat processed by or for the producers themselves is exempt from payment of the processing tax, and refunds of the processing tax are

made on the processed wheat distributed by charitable and relief organizations. It is estimated that the net return from the processing tax for the first year of operation of the wheat program will be about \$105,000,000. In making this estimate, allowance was made for the wheat processed by or for producers or for charitable or relief organizations.

The Agricultural Adjustment Administration does not believe, of course, that the production of wheat in the United States should be reduced to the absolute level of our own domestic requirements. There is always the possibility that a certain percentage of our wheat can be moved in export trade to advantage, and furthermore, it is necessary that a margin of safety be provided to insure that the United States will have enough wheat for its domestic requirements in the event we should have short crops. However, it is recognized that if this margin of safety is too wide it might have the effect of depressing the price of our wheat down to, or at least toward, the world level.

C. C. CONSER,

Agricultural Adjustment Administration.

WILD-LIFE Factors Intricately involved conditions confront those who seek the most desirable use of lands that are now forested or have been despoiled of their original forest cover and await the efforts of man to restore them to profitable production. Biological principles must be the foundation of the management practices designed to improve production and will govern their ultimate success. The many species of wild animal life inevitably enter the picture either as productive assets of forests, as factors in their establishment and maintenance, or as devastating agencies to limit returns or nullify toil and expenditures in forest improvement. It is the part of intelligent foresight to consider these three aspects of forest and wild-life relationships in planning for the utilization and improvement of forested lands and for the restoration of depleted areas to productivity.

Three Classes of Forest Fauna

The productive wild-life assets of forests include chiefly fur animals and upland game. Among the latter are grouse and turkeys; the upland game mammals include rabbits, squirrels, bears, deer, elk, and moose. In the list of fur-bearers are martens, fishers, minks, skunks, foxes, opossums, and raccoons. To meet the increasing demands for recreation, for profit to the landowner, and for support of the great manufacturing and outfitting industries dependent on adequate supplies of game and fur, it is desirable to maintain and increase these wild-life assets of the forests.

The wild-life factors in the establishment and maintenance of forests comprise the distributors and planters of seed and the destroyers of insects and other destructive agencies. Well known among the seed disseminators are the squirrels, chipmunks, and seed-eating birds, which in feeding, drop or plant nuts and seeds in places favorable for growth. The hosts of small creatures that search out insects and other small enemies of the forest thus tend to keep under natural control the populations that would otherwise become excessive. The impor-

tance of this constant repression is commonly overlooked because of its very effectiveness in affording continuous protection to the forests. The far-reaching importance of the continuing processes of natural control is brought forcefully to attention only as outbreaks of destructive agencies occur, and under favoring conditions get out of bounds.

The destructive wild-life agencies are species that multiply excessively or attack valued kinds of forest plants or animals at critical stages. The maintenance in proper proportion of the numbers of these plants and animals is the key to successful forest and wild-life management. Failure to recognize this fact and ineffectiveness in dealing with it have led to disastrous losses and to the failure of many otherwise promising undertakings in forest-improvement work. Well-known examples can be cited in the Kaibab deer surpluses, when starvation among the Arizona herds resulted from an inadequate food supply; and in the destruction of numerous forest plantings through failure first to study the injurious rodent situation and apply necessary preventive measures.

For nearly 50 years the Bureau of Biological Survey has been engaged in building up a body of knowledge regarding mammals, birds, reptiles, and amphibians, based on extensive surveys and the collection and classification of specimens and the compilation of records of occurrence, distribution, life histories, and habits. The Bureau has devoted much attention not only to the relationships that wild life sustains to agricultural crop and livestock production, but also to forestry. This work has served to bring into prominence the importance of the interplay of the materials and forces of nature and the principles on which nature works.

Forest-Fauna Research under McSweeney-McNary Act

In recent years the problems of wild life as they relate to forestry production have been attacked under far-sighted congressional authorizations. Comprehensive plans along major lines of approach to essential features are being put into effect as appropriations permit. These plans involve investigations of all forms of the forest fauna—rodents, predators, fur animals, game and nongame birds, and the reptiles and other lower forms.

Under this program the study of rodents includes their relation to grazing, erosion, and soil working; their effect on ground and tree-nesting birds, including species valued as game; their influence on tree seeding and growth, including beneficial and harmful activities; their role as destroyers of harmful or beneficial insects or other small invertebrates; their agency in carrying parasites and diseases; the determination of procedure for their effective control where they are unduly destructive, or for their protection and encouragement where they are beneficial; and observations of their breeding and feeding habits and movements as these relate to their economic status.

The carnivores are studied as to their value as fur producers and their influence on the welfare and abundance of other species. The harmful relationships of the predatory species involve destruction of game and livestock and their role as carriers of parasites and diseases communicable to man, or to game, livestock, or other valuable species. Investigations are made of their breeding habits in relation to abundance and destructiveness; the necessity for control measures; and the possibility of such control or protection as the situation requires.

Fur-bearing animals of forested and other areas are studied to determine their feeding, breeding, and other habits in relation to other useful or harmful wild life and their value in pelt production. The numbers that can be maintained profitably on a given area are determined, and means are provided for producing adequate numbers to meet commercial requirements. The regions in which furs are of best quality or are most satisfactory for commercial purposes are studied and mapped.

Investigations of game animals include observations on their feeding habits in relation to tree and shrubbery growth and to livestock grazing; ascertaining the numbers that can be maintained satisfactorily on given areas; developing means of maintaining proper game populations and harvesting the surplus; and reserving areas suitable for stocking with native species.

Investigations of birds are made of both game and nongame species. Studies of nongame birds cover the occurrence, abundance, distribution, life history, and the migrations of all forest-inhabiting species, their feeding habits, including injury or benefit to tree growth or reproduction and seed distribution; and their relation to beneficial or harmful species of insects, birds, rodents, or other small animals. Studies also are made of their relationships to food or game fish in forest streams and lakes, their possible agency in the dissemination of tree diseases, and means for the control of harmful and the increase of beneficial species.

Game-bird investigations are conducted to determine essential facts regarding their distribution, movements, habits, and habitat relationships, and the factors affecting their abundance. The study of feeding habits includes observation of any direct injury or benefit to forest reproduction or growth. Consideration is also given to the value of game birds as financial or recreational assets of the forests and to means of increasing their numbers where this is desirable.

Research on similar lines is contemplated in the case of reptiles and amphibians, with particular attention to poisonous species, including such monetary losses due to their presence as death of livestock or lowered grazing values of lands. Effort will be made to determine their relationship to rodent pests, to birds with beneficial habits, to fish that are utilized by man for food, to small game, and to fur-bearing animals. Experiments will also be conducted to determine practical methods for the control of such dangerous or harmful species as rattlesnakes, copperheads, and water moccasins; and to develop means for the protection and increase of useful species.

Practical Application of Wild-Life Studies

Problems of major importance in the various regions are given first attention, and results as obtained are made available for use in forest-improvement plans. Practical application of this research and fact-finding program was found to be of special importance from the viewpoint of wild-life considerations in the vast program of land utilization and forest improvement launched under the various relief and public-works undertakings of Federal and State Governments and in cooperation with private enterprise. Thus the Biological Survey was able to cooperate in the preparation of the wild-life sections of a recent special report (Senate Document No. 12) on A National Plan for American Forestry, and has been in position to serve in an advisory capacity on wild-life interests in the formulation and carrying into effect of such far-reaching national efforts as the forest-improvement operations of

the Civilian Conservation Corps, the Tennessee Valley improvement program, land-utilization plans of the Agricultural Adjustment Administration, and in the forestry, wild-life, and recreational undertakings under the National Recovery Administration.

W. B. BELL, *Bureau of Biological Survey.*

WOODLANDS Cut by the "Selection Method" Less Liable to Fire Damage

The greatest concern of many owners with regard to their farm woodlands and timbered areas is that fire may sweep over their land and destroy or seriously injure their forest growing stock. If the fire danger could be reduced, more landowners would be interested in using

FIGURE 112.—Cut-over area with canopy destroyed by fire. The fuels have dried out, and the chances of reproduction are very poor.

for continuous forest production lands that are too poor for agricultural crops. Thus the owner not only would obtain an additional crop, but also provide for himself and others profitable work that could be done at a time of year or during years when other work is at low ebb. Every timberland owner knows that if he cuts most or all of the trees on an area, this "opening up" lets in the sunlight and the hot, drying winds which were previously excluded by the dense forest canopy. Few owners, however, appreciate the effect of such openings in causing drier fuels and greater inflammability on the area and the danger which threatens not only the forest growth remaining after cutting but also all surrounding timber, adjacent buildings, etc. Tender young seedlings are exposed to the excessively high temperatures of full sunlight; sun scald and cat face are produced on saplings and poles; and the ground is so dried out that new seedlings are unable to obtain sufficient moisture to survive the period of maximum drought (fig. 112). Few even

of those who have noted such conditions have had occasion to measure them and consequently do not appreciate their full effects.

Some recent measurements made on fully timbered, half cut-over, and clear-cut land at the Priest River branch of the Northern Rocky Mountain Forest Experiment Station clearly indicate that these effects are very great. But they also show that it is possible to reconcile the desirable practice of cutting timber with the usually undesirable after effect of extreme drying. This reconciliation can be brought about by the so-called "selection" method of cutting, which removes the merchantable and the undesirable trees in the stand and yet retains enough crown canopy to shade the ground and the mat of leaves and twigs covering it. This shade is the best assurance that the soil moisture will be sufficient for seedlings and that the dead leaves and

FIGURE 113. — Canopy preserved after cutting. The fuels are protected from direct sunlight and the ground conditions are favorable to reproduction.

twigs on the ground will not become extremely dry and inflammable (fig. 113).

Table 10, summarizing these measurements, shows how clear cutting produces greater fire danger and how partial cutting assists in keeping the danger down.

TABLE 10. — *Measurement of factors in fire danger on uncut, half-cut, and clear-cut forest land, northern Idaho, Aug. 11-20, 1931*

Factor measured	Uncut area	Half-cut area	Clear-cut area
Average maximum air temperature.....°F..	83.9	86.9	90.6
Average relative humidity at 5 p.m.....percent..	23.4	19.0	16.8
Average wind movement.....miles per day..	2.0	24.8	49.6
Evaporation rate.....grams per period..	34.7	93.4	206.7
Average maximum temperature just below surface of duff.....°F..	78.8	93.6	133.3
Highest duff temperature.....do.....	85.0	102.0	148.0
Average moisture content of duff.....percent..	10.5	9.9	4.6
Average moisture of 2-inch diameter dead wood.....do.....	8.3	7.2	3.8

One of the most striking features in table 10 is the extremely high temperature of 148° F., measured just under the surface of the dead leaves and twigs forming the carpet of duff covering the mineral soil on the clear-cut area. At the surface of the duff, in the full blast of the sun, the temperature must have been even higher than 148° . As surface temperatures above 120° to 125° are dangerous to young seedlings, and temperatures of over 140° are generally fatal, the danger in such exposure to the sun is clear. Under the partial shade of the trees reserved from cutting, however, the temperature rose to only 102° , while under the almost complete shade of the undisturbed forest the maximum temperature in the duff rose to only 85° , or 1.1° above the lowest air temperature recorded.

Tree Crowns Absorb Direct Sunlight

These conditions illustrate the ability of the tree crowns to absorb direct sunlight, thereby preventing high temperatures in the ground and in the fuels on the ground. The remainder of the table shows that this resulted in an improvement of all those factors—air temperature, humidity, and evaporation rate—which make for drier fuels and faster spread of fire.

It is also evident in these measurements that removing half the timber canopy, in order to log the merchantable trees and to remove those that were diseased and otherwise defective and not worth their growing space, did not result in drying out the site to a condition half-way between that of the full-timbered and clear-cut areas. This is shown by the fact that the measurements on the half-cut area resemble more closely those for the fully timbered than those for the clear-cut area. In other words, although half the crown canopy was taken out, the danger was not increased proportionally.

One important fact should be remembered. After logging operations, the debris is usually burned, if it cannot be utilized profitably, and this burning must be done with extreme care in order to save all of the green canopy left. Very often there is plenty of shade available until the debris is burned, but because the burning is done at the wrong time of year, or because the debris is burned broadcast rather than in piles, all this beneficial shade is lost and the area becomes fully exposed and a future fire menace rather than a source of future revenue.

H. T. GISBORNE, *Forest Service.*

WOOL Yield and Fleece Density Can be Measured by a Simplified Method

Since returns from the wool of a flock of sheep depend to a large extent on the weight and quality of the fleeces, information concerning the shrinkage and other characteristics of wool is of practical value to growers. Owing to varying quantities of dirt and other foreign matter in wool, personal judgment, even among experienced sheepmen, is likely to involve serious error. For this reason the Department of Agriculture has developed a reasonably simple method for determining the yield of clean wool and also its density.

Obtaining and Preparing Sample

With clippers, a sample of wool is removed from the side of each sheep, and the cleared area is measured with special care. A clipper

that cuts a narrow swath, 1 or 2 inches wide, is well suited for the purpose. If many samples are to be taken a power clipper is desirable, owing to saving in time and labor. If barber's clippers are to be used, the comb and cutter should be so ground that the teeth of the lower blade extend slightly ahead of the upper blade, thereby permitting the cutter to feed through the wool. In any case, shearing should be close to the skin and the swath from 4 to 5 inches long. The weight of the samples will range from about 5 to 25 grams, depending on the quantity of grease and dirt present and the character of wool. Accurate measuring is best accomplished by holding the animal flat on its side. The wool is either weighed immediately on a scale accurate to one tenth of a gram, or put in a moisture-tight container and weighed later. After being weighed, the sample is placed, for cleaning, in an open-

FIGURE 114.—Taking sample for the determination of clean wool. If clean-wool yield alone is wanted, the sample need only be weighed. If density also is to be calculated, the clipped area must be measured.

mesh bag with an identification tag. About 25 of these bagged samples are placed in a larger open-mesh bag about the size of a pillowcase.

The method just described furnishes data on both the clean-wool yield and density. When only the clean-wool yield is desired, measurement of the sheared area is unnecessary, and larger samples weighing about 100 grams, or nearly 4 ounces, may be used. Such samples require less accurate weighing. An ordinary letter scale will give satisfactory results.

Figure 114 illustrates a clipped area which furnished a small sample, and the equipment used in obtaining it.

Cleaning the Sample

The unique feature of this method is that the weighed samples are drycleaned. Many samples of raw wool are thus cleaned satisfactorily at one time without felting. The procedure described is unsuitable for

use in connection with the usual scouring process in which warm soap and alkali solution are used. The reliability of the drycleaning method however, has been established by the close agreement in results obtained on samples drycleaned as compared with similar samples scoured individually in a soap-and-alkali solution. In the practical operation of the drycleaning method, which is the same for large and small samples, cleaning is accomplished by delivering the sack of samples to any commercial drycleaning plant equipped for thoroughly cleaning clothing. Instructions are given that the samples be cleaned by the same procedure used in drycleaning men's suits. The National Association of Dyers and Cleaners has cooperated in working out the details of the method here described.

A well-equipped drycleaning establishment ordinarily is able to clean as many as 200 samples in an hour. Any sand, chaff, or other impurity left in the wool after cleaning falls out as soon as the wool fibers are teased apart with the fingers. This is readily accomplished and requires only 3 or 4 minutes for a small sample and about 10 minutes for a large one. The clean samples, when thoroughly dry, are ready to be weighed again for determining yield and density.

The percentage of clean wool in a sample is calculated by dividing the weight of the cleaned sample by the original weight of the sample. This value may be applied to the weight of the entire fleece to obtain a measure of the clean-wool yield. From this clean-wool yield, and the size of the measured sheared area, the clean-wool yield per square inch may be calculated. Also, the grams of clean wool per cubic inch of the fleece may be obtained by dividing the weight of clean wool per square inch by the length of staple.

Through the cooperation of the experiment stations of three States, namely, Ohio, Pennsylvania, and West Virginia, this method has been tested for its suitability under practical conditions. As in the experimental work, the results agreed satisfactorily with those of similar samples scoured individually in the Department's wool-scouring laboratory at Beltsville, Md. The results proved to be a reliable basis for estimating the wool yield and density of the entire fleece. The method provides a more dependable guide than has heretofore been available to sheep growers in building up flocks for the production of heavy-shearing, light-shrinking fleeces, and thereby increasing efficiency in wool production.

J. I. HARDY, *Bureau of Animal Industry.*

ZINC Proves Useful in the Control of Some Plant Diseases

Salts of zinc have long been known to be germicides and fungicides, but owing to their mildness they have been neglected in favor of copper and sulphur compounds by plant pathologists in their search for effective fungicides. Recent discoveries, partly accidental, have shown the value of zinc in the control of two types of plant diseases. Though in 1914 a Frenchman had shown that zinc was essential as a minor soil element for the growth of corn, this fact remained obscure until American experiment stations (1926-28) showed that zinc was essential to the normal development of several families of plants.

With increasing severity the peach has been attacked in many Eastern States by a disease known as bacterial spot (fig. 115). As the peach

is injured by copper sprays, sulphur sprays were tested, but without success. Cultural methods and fertilizing proved of some help, but up to 4 years ago the control of this disease was still a problem. From 1928 to 1930 investigators in the Bureau of Plant Industry tested 200 different fungicides in the effort to find a remedy. Practically all were ineffective or injurious, but a zinc-lime mixture (4 pounds of zinc sulphate and 4 pounds of lime to 50 gallons of water) gave good control without injury to foliage or fruit. In fact, it stimulated the trees, and larger, darker-green leaves resulted.

The publication of these results by the Bureau of Plant Industry brought a new spray mixture into use, pulled zinc out of obscurity as a fungicide, and added one more to the meager list of spray-controlled bacterial diseases.

Rosette Disease of Pecans

Extensive new pecan plantings in the Southeast have been seriously affected by the disease known as rosette. Leaves on the diseased shoots are small, narrow, and condensed in bunches (fig. 116). In severe cases twigs and branches die back, and the tree becomes unproductive (fig. 117).

Researches carried on by the Bureau of Plant Industry had earlier brought out the fact that the disease is a noninfectious nutritional trouble resulting from soil conditions, and that humus-forming mulch or cover crops gave partial remedy. California experiment station workers, experimenting with apple rosette, a nutritional disease resembling pecan rosette, were successful with iron sulphate applied as a fertilizer, but found that the beneficial results were due to 1 percent of zinc carried as an impurity. The Department of Agriculture workers, who had also been using iron sulphate (both ferric and ferrous) successfully in a small way against pecan rosette, had dissolved the chemical in a galvanized-iron bucket and found the beneficial agent to be a zinc impurity derived from zinc in this container. Further experiments (1930-33) showed that zinc sulphate applied as a spray

FIGURE 115.—Bacterial spot of the peach.

in dilute solution, injected into the trunk, or applied to the soil like a fertilizer, would cure the disease.

FIGURE 116.—Pecan shoot and leaves affected with the rosette disease.

FIGURE 117.—A pecan tree that has been severely affected with the rosette disease for several years.

Zinc was thus proved to be one of the few materials that can be used in the successful treatment of diseased trees by injection.

M. B. WAITE, *Bureau of Plant Industry.*

AGRICULTURAL STATISTICS

Prepared under the direction of the statistical committee: Joseph A. Becker, chairman, Paul Froehlich, secretary, S. W. Mendum, V. N. Valgren, L. D. Howell, and F. J. Hosking.

The statistical section of this Yearbook brings together what seem from experience to be the most important agricultural statistics for the United States, and for the world so far as the agriculture of this country is concerned. Historical and geographical series have been given. Most of the data for earlier years, not covered in this Yearbook, will be found in past issues.

The crop and livestock reporting service estimates acreage, condition, yield per acre, production, and farm prices of crops, and numbers, production, farm prices, and values of livestock and livestock products. The organization of this work outside of the Crop Reporting Board and the office force in Washington consists of 40 State field offices, each with an agricultural statistician in charge. There is one field office for the New England States, one for Maryland and Delaware, one for Utah and Nevada, and one for Washington and Oregon.

Acreages for the year 1909 are as reported by the Bureau of the Census; acreages in 1919, 1924, and 1929 are based upon the census supplemented by State enumerations. In the intercensal years, from 1910 to 1915, estimated acreages were obtained by applying estimated percentages of decrease or increase to the published acreage in the preceding year. The estimates from 1916 to 1918, 1920 to 1923, 1925 to 1928, and 1930 to 1933 are based upon acreage changes from year to year as shown by a sample of over 2 percent of the crop acreages in each year, supplemented by State enumerations. Yields per acre are estimates based upon reports of one or more farmers in each agricultural township on the average yield per acre in their localities. For 1929 to 1933, yields for all crops except cotton have been adjusted to be comparable with yields derived from the census figures of 1919, 1924, and 1929. For all crops except cotton and a few minor crops, yields from 1919 to 1928 have been adjusted to be comparable with the census yields of 1919, 1924, and 1929. For these same crops, revisions of acreage have been made for the period 1919 to 1928 essentially to the acreages reported by the censuses of 1920 and 1930. For cotton, both acreage and yield have been revised to the basis of the 1930 census. Production is acreage times yield-per-acre figure. Linters are not included in cotton figures, unless so stated in the respective tables.

Estimates of farm stocks, sales, quality, crop condition, and miscellaneous information concerning crops are based either upon sample data or upon estimates of crop reporters for their localities.

The term "commercial" is used in connection with certain crop estimates to distinguish some part of the total production of a crop. Except for indicating that the entire production is not represented in the estimate, "commercial" does not have the same meaning in each instance where used. The commercial apple-crop estimate, for example, represents that portion of the total apple crop which is sold or available for sale for consumption as fresh fruit. That portion of the crop which is used for cider, vinegar, canning, evaporating, or other manufacture is not included in the commercial crop as defined in this case. The commercial orange and grapefruit crops in Florida represent the portion shipped or to be shipped as differentiated from the portion canned, made into juice, sold or consumed locally, wasted, etc.

Estimates of commercial truck-crop production are concerned only with those areas growing the crops primarily to supply the large consuming markets more or less distant from the producing center. Production in home and market gardens, intended principally for local sale, is excluded. Similarly with truck crops grown

for commercial canning or manufacture the estimates include only amounts grown for use by canning or packing establishments and exclude amounts canned in the home. For the commercial acreages in the areas concerned, the truck-crop estimates are intended to include the total production suitable for food marketing purposes (unless destroyed by natural cause before harvest) whether or not the entire crop finds a market or use. It is, therefore, customary practice to retain in the production estimates those quantities of produce which ordinarily would be marketable but which are left unharvested because of adverse marketing conditions. The canning crop estimates represent the total quantity of raw product used by packers or canners for manufacturing purposes, including cold-packing.

Monthly prices received by producers on the specified dates are based upon reports from special price reporters on the average price paid to farmers for the commodity, and they do not relate to any specified grade. These men are mostly country buyers of or dealers in agricultural products.

Farm values of crops as shown are mostly computed by applying the December 1 farm price to the total production. These prices are reported by the crop reporters, who are mostly farmers. The average price received for the portion of the crop sold may be greater or less than this price, depending upon the prices previous and subsequent to December 1, and the amount of the crop sold at the different prices. For the years 1919-33, weighted average prices for the crop-marketing season, and farm values based upon these weighted prices, have displaced the December 1 prices and values for many crops. The United States averages of prices computed in this manner differ slightly from those given in the tables showing monthly farm price estimates as well. This difference is due entirely to a slight variation in the method of computation. United States averages of monthly prices used in the calculation of farm values have been obtained by weighting State averages by estimated sales, while the basic data for the crop-year averages of prices for the country as a whole, shown with the monthly farm price data, were obtained by weighting State prices by total production.

For commercial truck crops and canning crops, and for certain fruit crops, the prices shown are the estimated season averages of the prices received by growers at the shipping point, the cost of the container included if a customary requirement of delivery. The December 1 price has been employed in computing farm values only in the case of certain miscellaneous crops of minor importance, where neither weighted averages of monthly prices nor estimates of average prices for the entire marketing season are available.

Numbers of livestock on farms on January 1, 1920, and 1925, are based upon the census enumeration as of that date, supplemented by enumerations by State agencies, such as assessors' and brand-inspection boards, and by records of shipments during 1920 and 1925. Numbers on January 1, 1930, give weight insofar as feasible to the numbers reported by the census of 1930 which was as of April 1, with allowance for indicated changes between January 1 and April 1. In the intercensal years, from 1911 to 1919, the numbers of livestock were obtained by methods similar to those used for crop acreages. Estimates from 1921 to 1924, from 1926 to 1929, and from 1931 to 1934 are based upon a sample of over 2 percent, supplemented by trends derived from assessors' enumerations, reports of brand-inspection boards, market movements, and stockyard receipts. The census bases are not always comparable from one decade to another, because of changes of dates and classifications.

The average value per head on January 1 is estimated from reports of correspondents relating to livestock in their vicinity. These tend to reflect inventory values as distinguished from the monthly prices which relate to sales. The farm value on January 1 is computed by applying the average value per head to the number on farms.

The Federal market news service supplies much of the information on market prices and movements. The leased-wire system in use by the service extends from the Atlantic to the Pacific and reaches most of the important markets of the country. At each of the branch offices commodity specialists gather information regarding the supply, the market demand, and prices for the products on which they report. They observe the sales actually made on the markets and are constantly in touch with the traders, who in many instances give them access to their office records in order that they may have specific information on which to base their reports. Car-lot shipments and market receipts of crops and livestock products are reported by officials and agents of railroads, express companies, and boat lines, or compiled from trade publications. Shipments to market by motor truck have continued important and at a few of these markets receipts by truck are reported by dealers and distributors. Data on receipts, slaughter, and shipments of livestock are obtained from monthly reports submitted by the public stockyards. Data on cold-storage stocks are obtained directly from all important cold-

storage warehouses, and data on commercial stocks of grain are reported by boards of trade, etc. Leaf-tobacco stocks are reported directly by dealers and manufacturers.

Where a weighting factor is available, market prices as shown are weighted averages; but in many cases a weighting factor is not available, and the prices shown are usually the means of ranges of quotations without reference to quantity.

Prices derived from different sources may not be strictly comparable although for most general purposes they are satisfactory. The data as to commercial stocks and movements of various commodities are as nearly complete as practicable and feasible, and are considered fairly representative.

The statistics of grain grading are based on work done by licensed grain inspectors located throughout the United States.

The tables of international trade cover substantially the international trade of the world. The total imports and the total exports in any one year cannot be expected to balance, although disagreements tend to be compensated over a series of years. Among the sources of disagreement are: The different periods covered by the "year" of various countries; imports received in the year subsequent to the year of export; lack of uniformity in classification of goods as among countries; different trade practices and varying degrees of failure in recording countries of origin and ultimate destinations; different practices in recording reexported goods; and different methods of treating free ports. The exports given are domestic exports and the imports given are imports for consumption whenever it is possible to distinguish such imports from general imports; that is, "special" or net instead of general. General imports are all imports reported. In foreign countries "special" trade is imports for consumption; or net imports, or imports less reexports. In the United States imports for consumption are those entered for actual consumption and include withdrawals from bonded warehouses for consumption. Special or net figures are used in the international trade tables for the following countries: Belgium, Denmark, Egypt, Irish Free State, China, Dutch East Indies, France, and United Kingdom. In the United States trade tables and wherever United States figures are given, they are domestic exports and general imports unless otherwise specified. While there are some inevitable omissions, there may be some duplication because of reshipments which do not appear as such in the official reports. In the trade tables, figures for the United States include Alaska, Puerto Rico, and Hawaii, but not the Philippine Islands or the Virgin Islands of the United States.

In order to make the statements of 1933 and 1934 prices and values comparable with similar data for earlier periods, there is given below a tabulation of the gold value of the dollar since April 1, 1933:

Gold value of the dollar, and dollar value of gold in London,¹ April 1933-March 1934

Date	Gold value of the dollar	Dollar value of gold per ounce		Date	Gold value of the dollar	Dollar value of gold per ounce		Date	Gold value of the dollar	Dollar value of gold per ounce	
		Actual	Relative			Actual	Relative			Actual	Relative
1933	Cents	Dollars		1933	Cents	Dollars		1933	Cents	Dollars

¹ Based on the open market price of gold in London, converted at the dollar exchange rate at the "fixing of the gold price" each day at 11 a.m. (London time).

² Par.

Bureau of Agricultural Economics. (Values are for Monday unless it falls on a holiday, when they are for the next business day.)

Statistics of acreage and production in foreign countries are compiled as far as possible from official sources and are therefore subject to whatever errors may result from shortcomings in the reporting and statistical services of the various countries. Inaccuracies also result from differences in nomenclature and classification in foreign countries. Except where otherwise stated, pre-war data refer to pre-war boundaries. Yields per acre are calculated from acreage and production, both rounded to thousand units, and are therefore subject to a greater possibility of error when calculated for countries with small acreage.

Agricultural Adjustment Administration work did not get under way until the middle of 1933. This issue of the Yearbook contains four summary tables, indicating in a general way some of the results of that work, but the reports are only preliminary and somewhat incomplete. These tables comprise the last pages in the section on Farm Business and Related Statistics.

As an aid to the comprehension and use of these statistics, the following table of weights, measures, and conversion factors will be useful. It represents the important basic figures, commonly used in the Department of Agriculture:

Weights, measures, and conversion factors used in the Department of Agriculture

Commodity	Unit ¹	Weight in pounds	Commodity	Unit ¹	Weight in pounds
Alfalfa seed	Bushel	60	Peanut oil	Gallon	7.5
Apricots	do	48	Potatoes	Bushel	60
Barley	do	48	Rapeseed	do	50
Beans, dry	do	60	Rice, rough	do	45
Buckwheat	do	48	Rice, milled	Pocket	100
Clover seed	do	60	Rye	Bushel	56
Corn, ear, husked	do	70	Soybean oil	Gallon	7.5
Corn, shelled	do	56	Spelt	Bushel	40
Cotton, ginned	Bale	500 478	Timothy seed	do	45
Cottonseed oil	Gallon	7.5	Tomatoes	do	56
Cranberries	Barrel	100	Wheat	do	60
Flaxseed	Bushel	56	Production of the following commodities is given in short tons: Almonds, apricots, avocados, broomcorn, cabbage, cherries, cottonseed, dates, figs, filberts, fruits for drying, grapes, hay, olives, plums and prunes, raisins, sugar, sugar beets, sugarcane, vegetables for manufacture, velvet-beans, and walnuts.		
Flour, various	Barrel	196			
Grain sorghums	Bushel	56			
Grapefruit (Florida)	Box	473			
Grapefruit (California)	do	460			
Hempseed	Bushel	44			
Lemons	Box	474			
Milk	Gallon	8.6			
Oats	Bushel	32			
Oranges (Florida)	Box	483			
Oranges (California)	do	470			
Orchard grass	Bushel	14			

Commodity	Unit	Equivalent to—
Almonds	1 pound shelled	About 3¼ pounds unshelled.
Apples	1 pound dried	About 7 pounds fresh.
Do.	1 barrel	3 boxes or 3 bushel baskets.
Barley flour	1 barrel (196 pounds)	About 9 bushels of barley.
Buckwheat flour	1 barrel (196 pounds)	About 7 bushels of buckwheat.
Filberts	1 pound shelled	About 2.22 pounds unshelled.
Malt	1.1 bushel	About 1 bushel of barley.
Oatmeal	1 barrel (196 pounds)	About 10¾ bushels of oats.
Peaches (California)	1 pound dried	About 5½ pounds fresh.
Peanuts	1 pound shelled	About 1½ pounds unshelled.
Prunes	1 pound dried	About 2½ pounds fresh in California; 3 to 4 pounds in other States.
Raisins	1 pound	About 4 pounds of fresh grapes.
Rye flour	1 barrel (196 pounds)	About 6 bushels of rye.
Walnuts, English	1 pound shelled	About 2.38 pounds unshelled.
Wheat flour	1 barrel (196 pounds)	About 4.7 bushels of wheat. ⁵

¹Standard bushel used in the United States contains 2,150.42 cubic inches; the gallon, 231 cubic inches.

²The standard weight of 70 pounds is usually recognized as being about 2 measured bushels of corn (husked) on the ear, as it requires 70 pounds to yield 1 bushel, or 56 pounds, of shelled corn.

³Gross.

⁴Net. The 478 pounds per net bale of cotton is only approximate.

⁵Due to changes in milling processes, equivalents used have varied as follows: 1790-1879, 5 bushels; 1880-1908, 4.75 bushels; 1909-17, 4.7 bushels; 1918 and 1919, 4.5 bushels; 1920, 4.6 bushels, and 1921-33, 4.7 bushels.

STATISTICS OF GRAINS

TABLE 1.—Wheat: Acreage, production value, foreign trade, etc., United States, 1890-1933

1933 ¹⁰	47,493	11.1	527,413	73.1	385,365						

¹ Beginning with 1919 prices are weighted average prices for crop marketing season.

² 1890-96, Bartel's Red Book, quoted as No. 2 spring; January 1897-June 1904, Chicago Daily Trade Bulletin, average of daily ranges; quotations used: January-October 1897, No. 3 spring; November 1897-June 1898, No. 3 spring, hard varieties; July 1898-June 1904, No. 1 spring; from February 1897, "free on board" was used when available; July 1904-December 1918, Bartel's Red Book, average of daily ranges, quoted as No. 1 northern. Subsequently from the Chicago Daily Trade Bulletin and are averages of the daily cash price per bushel weighted by car-lot sales.

³ Prices, 1890-98, are from the Price Current Grain Reporter 1924 Yearbook, p. 4, and are average cash prices for calendar years; subsequently from the Chicago Daily Trade Bulletin and are averages of the daily cash price per bushel weighted by car-lot sales.

⁴ Compiled from Commerce and Navigation of the United States, 1890-1917; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26; January and June issues, 1927-33. Wheat flour converted to terms of grain on the following basis: 1890-1908, 4.75; 1909-17, 4.7; 1918 and 1919, 4.5; 1920, 4.6; 1921-33, 4.7 bushels of grain per barrel of flour.

⁵ Includes flour milled from imported wheat.

⁶ Includes wheat imported for milling in bond and export.

⁷ Total exports (domestic plus foreign) minus total imports.

⁸ Weighted average for 11 months.

⁹ Weighted average for 10 months.

¹⁰ Preliminary.

Bureau of Agricultural Economics.

Production figures are estimates of the Crop Reporting Board, revised 1919-28. See introductory text; italic figures are census returns.

¹Includes all Russian territory reporting for years named.²Total Russian Empire exclusive of the 10 Vistula Provinces of Russian Poland and the Province of Batum in Transcaucasia.³Exclusive of Russian Poland, Lithuania, parts of present Latvia and Ukraine, and 2 Provinces of Transcaucasia.⁴Beginning with this date estimated production is within present boundaries of the Union of Socialist Soviet Republics, excluding Turkestan, Transcaucasia, and the Far East, which regions in 1924 produced 51,706,000 bushels and, in 1925, 58,000,000 bushels.⁵Beginning with this date production is within post-war boundaries and therefore not comparable with earlier years.⁶Preliminary.

Bureau of Agricultural Economics.

Production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere which immediately follow; thus, for 1933-34 the crop harvested in the Northern Hemisphere countries in 1933 is combined with the Southern Hemisphere harvest which begins late in 1933 and ends early in 1934.

1 Preliminary.

2 Year 1925.

3 Area sown.

4 Computed on sown acreage.

Bureau of Agricultural Economics. Official sources and International Institute of Agriculture. Both acreage and production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere which immediately follow; thus, for 1933-34 the crop harvested in the Northern Hemisphere countries in 1933 is combined with the Southern Hemisphere harvest which begins late in 1933 and ends early in 1934.

Bureau of Agricultural Economics. Compiled from reports of licensed inspectors through district offices of Federal grain inspection. The quantity loaded per car varies, but car-lot receipts have been converted to bushels by using conversion factors for crop years as follows: 1924-25, 1,559; 1925-26, 1,368; 1926-27, 1,380; 1927-28, 1,399; 1928-29, 1,441; 1929-30, 1,455; 1930-31, 1,477; 1931-32, 1,485; 1932-33, 1,479; and 1933-34, 1,500 bushels per car respectively.

Bureau of Agricultural Economics. Compiled from reports of licensed inspectors through district offices of Federal grain inspection. See 1927 Yearbook, p. 752, and 1928 Yearbook, p. 683, for data for earlier years. The quantity loaded per car varies, but car-lot receipts have been converted to bushels by using the following conversion factors: 1928-29, 1,441; 1929-30, 1,455; 1930-31, 1,477; 1931-32, 1,485; and 1932-33, 1,479 bushels per car respectively.

¹ Includes domestic wheat in store in public and private elevators in 41 markets and wheat afloat in vessels or barges in harbors of lake and seaboard ports. Does not include wheat in transit either by rail or water, stocks in mills, or mill elevators attached to mills, or private stocks of wheat intended for local use.

² Includes United States wheat in store at 15 Canadian points or afloat in vessels or barges in the harbors of lake and seaboard ports. Does not include wheat in transit to Canadian ports.

³ Includes practically all Canadian wheat held within Canadian boundaries, exclusive of farm and certain mill stocks.

⁴ Includes Canadian wheat in store and afloat at 10 United States lake and seaboard ports but not Canadian wheat in transit on lakes or canals.

Bureau of Agricultural Economics; compiled from weekly reports to the grain, hay, and feed market news service. Data are for stocks on the Saturday nearest the 1st day of the month.

TABLE 14.—*Wheat: United States production, 1928-29 to 1933-34, and exports by classes, 1923-24 to 1932-33*

¹ White wheat in the Pacific Northwest region consists of both spring and winter wheat; no attempt has been made to classify this wheat as other than white wheat, part of which is spring and part winter.

² Mixed wheats exported from Atlantic coast ports are estimated as approximately 70 percent durum and the remainder as hard red spring; that exported from Gulf ports as approximately half and half hard and soft winter; and that exported from Pacific coast ports as approximately 90 percent white and the remainder as hard and soft red winter wheats.

³ Designations by classes include all inspections for export. Flour as wheat is as reported by customs offices. "Other wheat" comprises total domestic exports as reported by customs offices minus "inspections for export" and consists principally of exports through Canada from customs districts of Buffalo, Chicago, Duluth-Superior, Ohio, and Wisconsin.

Bureau of Agricultural Economics.

Estimated production by classes based on questionnaire surveys of local authorities; supplemented by judgment of cereal specialists. Inspections of United States wheat for export data furnished monthly by Federal grain supervision officers at the export markets. Inspections are made at the ports of export. Export figures from reports of the Bureau of Foreign and Domestic Commerce.

¹ Preliminary.

Bureau of Agricultural Economics; compiled from Monthly Summary of Foreign Commerce of the United States.

The following factor has been used for converting flour into terms of wheat: 1 barrel of flour = the product of 4.7 bushels of grain.

¹ Average of daily prices weighted by car-lot sales.

² Compiled from daily trade papers of markets named. The prices in this section of the table are comparable with prices City, St. Louis, Omaha, and Duluth. The prices in this section of the table are comparable with prices paid to producers in that the latter are averages of the several prices reported which cover all classes and grades sold by producers.

Bureau of Agricultural Economics; compiled from Minneapolis Daily Market Record, St. Louis Daily Market Reporter, and Kansas City Grain Market Review.

¹Beginning with 1919 prices are weighted average prices for crop marketing season.²Prices are from Minneapolis Daily Market Record and are averages of daily prices weighted by car-lot sales.³Compiled from Commerce and Navigation of the United States, 1909-17; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26; January and June issues, 1927-33, and official records of the Bureau of Foreign and Domestic Commerce. Rye—General imports, 1909; imports for consumption, 1910-33. Rye flour—Imports for consumption, 1909-33. Rye flour converted to rye on the basis that 1 barrel of rye flour is the product of 6 bushels of grain.⁴Total exports (domestic plus foreign) minus total imports.⁵Net imports.⁶Preliminary.

Bureau of Agricultural Economics.

Production figures are estimates of the Crop Reporting Board, revised 1919-28. See introductory text; italic figures are census returns. See 1927 Yearbook, p. 764, for data for earlier years.

1 Preliminary.

2 4-year average.

3 Area sown.

4 Computed from sown acreage.

Bureau of Agricultural Economics.

Both acreage and production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere with the immediately follow; thus, for 1933-34 the crop harvested in the Northern Hemisphere countries in 1933 is combined with the Southern Hemisphere harvest which begins late in 1933 and ends early in 1934.

¹ Includes domestic rye in store in public and private elevators in 41 markets and rye afloat in vessels or barges in harbors of lake and seaboard ports. Does not include rye in transit either by rail or water, stocks in mills, or mill elevators attached to mills, or private stocks of rye intended for local use.

² Includes United States rye in store at 15 Canadian points or afloat in vessels or barges in the harbors of lake and seaboard ports. Does not include rye in transit to Canadian points.

³ Includes practically all Canadian rye held within Canadian boundaries, exclusive of farm and certain mill stocks.

⁴ Includes Canadian rye in store and afloat at 10 United States lake and seaboard ports but not Canadian rye in transit on lakes or canals.

Bureau of Agricultural Economics; compiled from weekly reports to the grain, hay, and feed market news service.

Data are for stocks on the Saturday nearest the 1st day of the month.

¹ Beginning with 1919 prices are weighted average prices for corn marketing season.

² Prices 1890-98 are averages of the weekly quotations for No. 2 or better in annual reports of Chicago Board of Trade; subsequent prices are compiled from the Chicago Daily Trade Bulletin, average of daily prices weighted by car-lots sales, No. 3 yellow.

³ Compiled from Commerce and Navigation of the United States, 1890-1917; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States, June issues 1919-26; January and June issues, 1927-33 and official records of the Bureau of Foreign and Domestic Commerce. Corn—General imports 1890-1909 and 1912-33; imports for consumption 1910 and 1911. Corn meal—Imports for consumption, 1890-1933. Corn meal converted to terms of grain on the basis of 4 bushels of corn to a barrel of meal.

⁴ Total exports (domestic plus foreign) minus total imports.

⁵ Net imports, i.e., total imports minus total exports (domestic plus foreign).

⁶ Corn harvested for grain; total acreage of corn in 1924 is 98,401,627 acres; 1929, 97,740,740 acres.

⁷ Preliminary.

Bureau of Agricultural Economics.

Production figures are estimates of the Crop Reporting Board, revised, 1919-28. See introductory text; italic figures are census returns. See 1927 Yearbook, p. 774, for data for earlier years.

TABLE 41.—Corn: Acreage, yield, production, and weighted average price per bushel received by producers, by States, averages, and annual 1932 and 1933

State and division	Acreage harvested			Yield per acre			Production			Price for crop of—

¹ Includes all Russian territory reporting for the years shown.² Total Russian Empire exclusive of the 10 Vistula Provinces of Russian Poland and the Province of Batum in Transcaucasia.³ Exclusive of Russian Poland, Lithuania, parts of present Latvia and the Ukraine, and the Provinces of Batum and Elizabetpol in Transcaucasia.⁴ Beginning this year, estimates within present boundaries of the Union of Socialist Soviet Republics, exclusive of Turkestan, Transcaucasia, and the Far East, which territory in 1924-25 produced 26,048,000 bushels.⁵ Production in present boundaries beginning this year, therefore not comparable with earlier years.⁶ Preliminary.

Bureau of Agricultural Economics; official sources and International Institute of Agriculture.

Production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere which immediately follow; thus, for 1932-33 the crop harvested in the Northern Hemisphere countries in 1932 is combined with the Southern Hemisphere harvest which takes place early in 1933.

TABLE 44.—Corn: Acreage, yield per acre, and production in specified countries, average 1921-22 to 1925-26, annual 1930-31 to 1933-34

¹ Preliminary. ² 2-year average. ³ 3-year average. ⁴ Planted acreage. The area lost is estimated at about 3,700,000 acres. ⁵ European cultivation only.

Bureau of Agricultural Economics; official sources and International Institute of Agriculture.
Both acreage and production figures refer to the year of harvest. Harvests of the Northern Hemisphere which are combined with those of the Southern Hemisphere in 1932 are combined with the Southern Hemisphere harvest which takes place early in 1933. Immediately follow; thus for 1932-33 the crop harvested in the Northern Hemisphere in 1932 is combined with the Southern Hemisphere harvest which takes place early in 1933.

¹ Includes domestic corn in store in public and private elevators in 41 markets and corn afloat in vessels or barges in harbors of lake and seaboard ports. Does not include corn in transit either by rail or water, stocks in mills, or mill elevators attached to mills, or private stocks of corn intended for local use.

² Includes United States corn in store at 15 Canadian points or afloat in vessels or barges in the harbors of lake and seaboard ports. Does not include corn in transit to Canadian ports.

Bureau of Agricultural Economics; compiled from weekly reports to the grain, hay, and feed market news service.

Data are for stocks on the Saturday nearest the first day of the month.

¹ Average of daily prices weighted by car-lot sales.

² Compiled from daily trade papers of markets named. The markets are Chicago, St. Louis, Omaha, Kansas City, Minneapolis, and Cincinnati (not included since November 1928). The prices in this section of the table are comparable with prices paid to producers in that the latter are averages of the several prices reported which cover all classes and grades sold by producers.

Bureau of Agricultural Economics; compiled from Chicago Daily Tribune Bulletin and Kansas City Grain Market Review.

Bureau of Agricultural Economics. Compiled as follows: Buenos Aires, Boletín Oficial de la Bolsa de Comercio de Buenos Aires, averages of daily quotations, converted at monthly average rates of exchange as given in Federal Reserve Bulletin; Liverpool, Broomhall's Corn Trade News, averages of Tuesday quotations through Feb. 19, 1929. Beginning Feb. 27, 1929, Wednesday quotations were used. Converted at monthly average rates of exchange as given in Federal Reserve Bulletin, except for period January 1926 to August 1931, when par of exchange was used.

¹ Beginning with 1919 prices are weighted average prices for crop marketing season.² From Chicago Daily Trade Bulletin, averages of the daily cash quotations of No. 3 white oats weighted by car-lot sales.³ Compiled from Commerce and Navigation of the United States, 1900-1917; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26; January and June issues, 1927-33; and official records of the Bureau of Foreign and Domestic Commerce. Oats—general imports, 1900-1933; oatmeal—general imports, 1900-1909; imports for consumption, 1910-33.⁴ Total exports (domestic plus foreign) minus total imports.⁵ Net imports. Total imports minus total exports (domestic plus foreign).⁶ Less than 0.05 percent.⁷ Preliminary.

Bureau of Agricultural Economics.

Production figures are estimates of the Crop Reporting Board, revised, 1919-28. See introductory text; italic figures are census returns. See 1927 Yearbook, p. 788, for data for earlier years.

¹ Includes all Russian territory reporting for the years shown.² Total Russian Empire, exclusive of the 10 Vistula Provinces of Russian Poland and the Province of Batum in Transcaucasia.³ Exclusive of Russian Poland, Lithuania, parts of present Latvia and the Ukraine, and the Provinces of Batum and Elizabetpol, in Transcaucasia.⁴ Beginning this year, estimates for the present territory of the Union of Socialist Soviet Republics, exclusive of Turkestan, Transcaucasia, and the Far East, which territory in 1924-25 produced 20,248,000 bushels.⁵ Beginning with this year post-war boundaries, and therefore not comparable with earlier years.⁶ Preliminary.

Bureau of Agricultural Economics; official sources and International Institute of Agriculture.

Production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere which immediately follow; thus, for 1933-34 the crop harvested in the Northern Hemisphere countries in 1933 is combined with the Southern Hemisphere harvest which begins late in 1933 and ends early in 1934.

¹ Includes domestic oats in store in public and private elevators in 41 markets and oats afloat in vessels or barges in harbors of lake and seaboard ports. Does not include oats in transit either by rail or water, stocks in mills, or mill elevators attached to mills, or private stocks of oats intended for local use.

² Includes United States oats in store at 15 Canadian points or afloat in vessels or barges in the harbors of lake and seaboard ports. Does not include oats in transit to Canadian ports.

³ Includes practically all Canadian oats held within Canadian boundaries, exclusive of farm and certain mill stocks.

⁴ Includes Canadian oats in store and afloat at 10 United States lake and seaboard ports but not Canadian oats in transit on lakes or canals.

Bureau of Agricultural Economics; compiled from weekly reports to the grain, hay, and feed market news service.

Data are for stocks on the Saturday nearest the 1st day of the month.

¹ Beginning with 1919 prices are weighted average prices for crop marketing season.² From Bureau of Labor Statistics as follows: Bulletin No. 39, 1900-1901. August 1900-December 1901, Choice to Fancy malting, by samples. Wholesale price bulletins—monthly quotations, January 1902-December 1913, Choice to Fancy malting; January 1914-September 1927, Fair to Good malting. Beginning October 1927, grade reported as feeding, but as quality remained unchanged, no change was made in comparative prices.³ Compiled from Commerce and Navigation of the United States, 1900-1917: Foreign Commerce and Navigation of the United States, 1918: Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26; January and June issues, 1927-33; and official records of the Bureau of Foreign and Domestic Commerce. Malt converted to terms of barley on the basis that 1.1 bushels of malt is the product of 1 bushel of barley. Barley flour converted on the basis that 1 barrel of flour is the product of 9 bushels of barley. Exports of flour not reported prior to 1919. Barley—general imports, 1900-1909; imports for consumption, 1910-33. Malt—general imports, 1909-14; imports for consumption, 1915-33. Imports of flour not reported prior to 1915; imports for consumption, 1915-33.⁴ Total exports (domestic exports plus reexports) minus total imports.⁵ Average for 11 months.⁶ Net imports. Total imports minus total exports (domestic plus foreign).⁷ Preliminary.

Bureau of Agricultural Economics.

Production figures are estimates of the Crop Reporting Board, revised, 1919-28. See introductory text; italic figures are census returns. See 1927 Yearbook, p. 799, for data for earlier years.

¹ Includes all Russian territory reporting for the years shown.² Total Russian Empire exclusive of the 10 Vistula Provinces of Russian Poland and the Province of Batum in Transcaucasia.³ Exclusive of Russian Poland, Lithuania, parts of present Latvia and the Ukraine, and 2 Provinces of Transcaucasia.⁴ Beginning this year, estimates within present boundaries of the Union of Socialist Soviet Republics excluding Turkestan, Transcaucasia, and the Far East, which regions in 1924-25 produced 20,897,000 bushels.⁵ Post-war boundaries beginning this year, and therefore not comparable with earlier years.⁶ Beginning this year weighed bushels, those reported for the earlier years being measured bushels.⁷ Spring barley only, which usually comprises about 95 percent of the total.⁸ Preliminary.

Bureau of Agricultural Economics; official sources and International Institute of Agriculture. Production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere which immediately follow; thus, for 1933-34 the crop harvested in the Northern Hemisphere countries in 1933 is combined with the Southern Hemisphere harvest which begins late in 1933 and ends early in 1934.

¹ Preliminary. ² Spring barley only, which usually comprises about 95 percent of the total. ³ 2-year average. ⁴ 1 year only. ⁵ 4-year average. ⁶ Acreage sown. ⁷ Yield per acre sown.
 Bureau of Agricultural Economics: official sources and International Institute of Agriculture.
 Both acreage and production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere which immediately follow theirs, for 1932-33 the crop harvested in the Northern Hemisphere countries in 1932 is combined with the Southern Hemisphere harvest which begins late in 1932 and ends early in 1933.

¹ Includes domestic barley in store in public and private elevators in 41 markets and barley afloat in vessels or barges in harbors of lake and seaboard ports. Does not include barley in transit either by rail or water, stocks in mills, or mill elevators attached to mills, or private stocks of barley intended for local use.

² Includes United States barley in store at 15 Canadian points or afloat in vessels or barges in the harbors of lake and seaboard ports. Does not include barley in transit to Canadian ports.

³ Includes practically all Canadian barley held within Canadian boundaries, exclusive of farm and certain mill stocks.

⁴ Includes Canadian barley in store and afloat at 10 United States lake and seaboard ports but not Canadian barley in transit on lakes or canals.

Bureau of Agricultural Economics; compiled from weekly reports to the grain, hay, and feed market news service.

Data are for stocks on the Saturday nearest the 1st day of the month.

¹ Beginning with 1919 prices are weighted average prices for crop marketing season.² The figures shown, 1909-20, are averages of daily closing prices compiled from annual reports of the Minneapolis Chamber of Commerce; beginning 1921 averages of daily prices weighted by car-lot sales, compiled from Minneapolis Daily Market Record.³ Compiled from Commerce and Navigation of the United States, 1909-17; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States June, July, and August issues, 1919-26. January, June, July, and August issues, 1927-33, and official records of the Bureau of Foreign and Domestic Commerce. 1 bushel of flaxseed weighs 56 pounds; 1 bushel of seed yields approximately 2½ gallons of oil; and 1 gallon of oil weighs 7½ pounds.⁴ Preliminary.

Bureau of Agricultural Economics.

Production figures are estimates of the Crop Reporting Board, revised, 1919-28. See introductory text; italic figures are census returns. See 1927 Yearbook, p. 809, for data for earlier years.

¹ Excludes a few minor producing countries for which no statistics are available and which do not enter into world trade.² Flax and hemp.³ Estimate of Bureau of Agricultural Economics.

Bureau of Agricultural Economics; official sources and International Institute of Agriculture.

Production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere, which immediately follow; thus, for 1932-33 the crop harvested in the Northern Hemisphere countries in 1932 is combined with the Southern Hemisphere harvest which begins late in 1932 and ends early in 1933.

¹ Preliminary.² Flax and hemp.³ 4-year average.⁴ 2-year average.⁵ Where changes in territory have occurred averages are estimates for territory within present boundary.⁶ Acreage figures are for area sown; hectares of area harvested are not available for all years; but over a 16-year period the harvested area averaged 10 percent below the sown area.⁷ Excludes a few minor producing countries for which no statistics are available and which do not enter into world trade.

Bureau of Agricultural Economics; official sources and International Institute of Agriculture.

Both acreage and production figures refer to the year of harvest. Harvests of the Northern Hemisphere in 1930 are combined with the Southern Hemisphere harvest which begins late in 1930 and ends early in 1931.

¹ Includes domestic flaxseed in store in public and private elevators in 41 markets and flaxseed afloat in vessels or barges in harbors of lake and seaboards ports. Does not include flaxseed in transit either by rail or water, stocks in mills, or mill elevators attached to mills, or private stocks of flaxseed intended for local use.

² Includes practically all Canadian flaxseed held within Canadian boundaries, exclusive of farm and certain mill stocks.

Bureau of Agricultural Economics; compiled from weekly reports to the grain, hay, and feed market news service.

Data are for stocks on the Saturday nearest the 1st day of the month.

¹ China is an important producing country, but official statistics are not available. The Shanghai office of the Bureau of Agricultural Economics has made the following estimates of production in China: 1930, 50,600,000 short tons; 1931, 38,180,000 tons; 1932, 49,000,000 tons; 1933, 46,800,000 tons.

² Estimates of the production of rice on nonirrigated land are not available prior to 1917-18. Estimates for the years 1909-10 to 1916-17 as given here are for the production on irrigated land. Estimates for the years 1917-18 to 1933-34 are for the total production.

³ Estimated figures obtained by multiplying acreage under rice as classified for revenue purposes up to 1912-13, and acreage as reported by the Department of Land and Agriculture from 1912-13 on by an average yield for the years 1920-21 to 1923-24, for which years official estimates have been published of acreage, yield, and total production.

⁴ Preliminary.

Bureau of Agricultural Economics.

Production figures refer to the year of harvest. Harvests of the Northern Hemisphere countries are combined with those of the Southern Hemisphere which immediately follow; thus, for 1932-33 the crop harvested in the Northern Hemisphere countries in 1932 is combined with the Southern Hemisphere harvest which begins late in 1932 and ends early in 1933. Estimates of world rice production for the period 1909-1931 to 1908-9 appear in Agriculture Yearbook 1924, p. 653.

¹ Preliminary.² Includes 9 months' land trade.³ Sea trade only.⁴ Year ending Mar. 31 of following year.⁵ Java and Madura only.⁶ International Yearbook of Agricultural Statistics.

Bureau of Agricultural Economics; official sources except where otherwise noted.

Mostly milled rice. Under rice is included paddy, unhulled, rough, milled, polished, broken, and cargo rice, in addition to rice flour and meal. Rice bran is not included. Rough rice, or paddy, where specifically reported, has been reduced to terms of milled rice at the ratio of 162 pounds of rough or unhulled to 100 pounds of milled. "Rice, other than whole or cleaned rice", in the returns of the United Kingdom is not considered paddy, since the chief sources of supply indicate that it is practically all hulled rice. Cargo rice, a mixture of hulled and unhulled, is included without being reduced to terms of milled. Broken rice and rice flour and meal, are taken without being reduced to terms of whole milled rice.

¹ Compiled from Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26; January and June issues, 1927-33 and official records of the Bureau of Foreign and Domestic Commerce. Buckwheat—imports for consumption, 1919-24 and 1930-33—general imports, 1925-26; buckwheat flour imports for consumption 1919-33. Buckwheat flour converted to terms of grain on the basis that 1 barrel of flour is the product of 7 bushels of grain.² The difference between total exports (domestic exports plus reexports) and total imports. Net exports indicated by +; net imports indicated by -.³ Preliminary.

Bureau of Agricultural Economics.

Production figures are estimates of the Crop Reporting Board, revised, 1919-28. See introductory text; italic figures are census returns. See 1927 Yearbook, p. 825, for data for earlier years.

1933		40,929	40,144	200.4	13,177	9.17	604,376				

¹ For 1909-26, inclusive, the acreage figures relate to June 25 instead of July 1.

² Agricultural census figures for all periods and department figures prior to 1899 are in running bales; 500 pound gross weight bales, 1899-1933.

³ Beginning with 1908 prices are weighted average prices for crop marketing season.

⁴ New York prices 1890-99 from the Commercial and Financial Chronicle; beginning 1900 from reports of the New York Cotton Exchange except Sept. 23-Nov. 16, 1914, when the exchange was closed (prices for this period from the Commercial and Financial Chronicle). New Orleans prices were from same sources prior to Aug. 16, 1915, since which date from reports of the New Orleans Cotton Exchange direct to this Bureau. These central market prices are for Middling grade, 7/8-inch staple, only.

⁵ Excluding linters from 1914 to 1933.

⁶ Compiled from Commerce and Navigation of the United States, 1890-1917; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States, June and July 1919-33, and January 1927-33.

⁷ Bales of 500 pounds gross weight.

⁸ Bales of 478 pounds net, which are equivalent to bales of 500 pounds gross weight.

⁹ Total exports (domestic plus foreign) minus imports.

¹⁰ Average for 9 months only. Exchange closed Aug. 1-Nov. 17, on account of war.

¹¹ Preliminary.

¹² Area in cultivation July 1 less removal of acreage reported by the Agricultural Adjustment Administration, less abandonment on area not under contract.

Bureau of Agricultural Economics.
Agricultural census figures in italics; other acreage, yield, and production figures are estimates of the Crop Reporting Board. Production figures conform with census annual ginning enumerations, with allowance for cross State ginnings. State figures rounded to thousands and added for United States total. Since the 1933 Yearbook was published, acreage and yield for all years have been revised to the level of the 1936 census, and cotton grown in Baja California, ginned in California, from 1913 to 1924 has been excluded.

¹ From reports of the Chinese Cotton Statistics Association, except for 1933-34, which is the estimate of this Bureau. Figures represent the crop in the most important cotton-producing Provinces where the commercial crop is grown. Most of the cotton produced in other provinces is used for home hand-loom consumption.

² Figures as reported by the U.S. Bureau of the Census, including the cotton destined to enter commercial channels for factory purposes. Estimates of the commercial crop in China are included.

³ Bales of 478 pounds net.

⁴ American in running bales and foreign in bales of 478 pounds net, beginning with 1922-23. From 1909-10 to 1916-17, inclusive, bales of 500 pounds net, and from 1917-18 to 1921-22 in bales of 478 pounds net.

⁵ Preliminary.

Bureau of Agricultural Economics; from official sources, International Institute of Agriculture, and estimates of the Bureau of Agricultural Economics, except as noted.

The crop year is from Aug. 1 to July 31. For the United States prior to 1914 the figures apply to the year beginning Sept. 1.

¹ Production is expressed in running bales in this table and therefore the figures are not the same as those shown in tables where bales of 500 pounds gross weight are used. Consumption and carry-over statistics for American cotton are available only in running bales, and therefore production and exports are shown in running bales.

² Total distribution usually is greater than total supply due principally to the inclusion, in all distribution items, of the "city crop", which consists of rebaled samples and pickings from cotton damaged by fire and weather.

Bureau of Agricultural Economics; compiled from Bureau of Census reports.

Quantities are in running bales, round bales counted as half bales and foreign in 500-pound bales.

¹ Year beginning Aug. 1, except 1913, which is the year beginning Sept. 1.

² "American" cotton means cotton which is grown in the United States.

³ American in running bales and other growths in bales of 478 pounds net. Prior to 1919-20 the quantities given for world consumption of all growths were reported in bales of 500 pounds net and have been converted to equivalent 478-pound bales.

Bureau of Agricultural Economics; compiled from reports of the Bureau of the Census except consumption figures for American cotton in foreign countries, which are compiled from the New York Cotton Exchange Service Basic Data, p. 37.

The figures for the consumption of "other growths" in the world and in foreign countries were computed by deduction.

¹ Preliminary.² 3-year average.³ Calendar year.

Bureau of Agricultural Economics; official sources except where otherwise noted.

Bales of 500 pounds gross weight or 473 pounds net. The figures for cotton refer to ginned and unginned cotton, but do not include linters, mill waste, cotton batting, scarto (Egyptian and Sudan), when separately stated. Wherever unginned cotton has been separately stated in the original reports it has been reduced to ginned cotton in this statement at the ratio of 3 pounds unginned to 1 pound ginned.

¹ Year shown is that in which beets were grown. Sugar-making campaign extends into succeeding year.

² Including, in some years, a small acreage in Canada used by United States factories.

³ Includes a small quantity not made from beets, and also that made at the Johnstown, Colo., molasses factory.

⁴ Percentages of sucrose (pure sugar) in the total soluble solids of the beets.

⁵ Based upon weight of beets sliced, except possibly in a very few factories.

⁶ Sucrose actually extracted by factories, including that recovered from beet molasses.

⁷ Preliminary.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

¹ Cane sugar, raw, converted to refined basis by multiplying by the following factors: United States, 0.932; Puerto Rico, 0.9293; Hawaii, 0.938; Philippine Islands, 0.95.

² Figures for 1909-10 to 1923-24 include Louisiana and Texas; beginning 1924-25, Louisiana only.

³ Unofficial estimate of centrifugal only.

⁴ Preliminary.

⁵ Unofficial.

Bureau of Agricultural Economics; production data compiled from the following sources: United States from the Department of Agriculture, except cane sugar, 1909-10 and 1919-21, which are from Willet & Gray; Hawaii from Hawaiian Sugar Planters' Association; Puerto Rico and Philippines from official sources of those islands.

Figures for earlier years appear in previous issues of the Yearbook.

¹Sugar campaign, usually not ended before February following season of growth of cane.²The growth of about 9 months.³1 ton of sugar as made is assumed to be equivalent to 0.932 ton of refined as tentatively recommended by the joint committee on sugar statistics of the Departments of Commerce and Agriculture.⁴Based upon tonnage of cane used.⁵Figures for molasses, 1911-14, are as reported by the Louisiana Sugar Planters' Association; figures for later years as reported by Division of Crop and Livestock Estimates. For sirup production, see table 149.⁶Preliminary.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

¹ Beet and cane sugar only.² Duty free, from Hawaii, Puerto Rico, and the Philippine Islands (Virgin Islands included in 1917 and subsequently).³ No account taken of sugar imported in other forms. Imports from the Philippine Islands excluded, reexports deducted.⁴ Shipments to Hawaii and Puerto Rico included. Direct exports to foreign countries from Hawaii and Puerto Rico excluded.⁵ Sugar used in the manufacture of other commodities for export on which drawback was paid.⁶ No account taken of stocks at the beginning or end of year.⁷ Raw sugar converted to refined by multiplying by the following factors: Cuba and Hawaii, 0.888; Puerto Rico, 0.9393; Philippines, 0.95; all others (Santo Domingo, British West Indies, Louisiana, etc.), 0.932. Use reciprocal of above factors to reduce refined sugar to raw.

Bureau of Agricultural Economics; trade figures from the Bureau of Foreign and Domestic Commerce.

¹ Figures are for the crop years 1909-10 to 1933-34 for the countries in which the sugar production season begins in the fall months and is completed during the following calendar year, except in certain cane-sugar-producing countries where the season begins in May or June and is completed in the same calendar year. Production in these countries is for the calendar years 1909-33.

² Production of cane and beet sugar in terms of raw sugar.

³ The figures quoted for India are for the production of gur, a low grade of sugar polarizing between 50° and 60°. Practically the entire crop is consumed within the country.

⁴ All grades of sugar reduced to terms of head sugar, a grade of sugar which contains at least 96.5 percent sucrose. Figures for Java are for the calendar years 1910-34.

⁵ Figures for 1909-10 to 1917-18 are for pre-war boundaries.

⁶ Figures are incomplete through 1920-21; 1914-15 includes Prussian Poland only; 1915-16 to 1919-20 include Prussian Poland and Congress Poland; 1920-21 includes Prussian Poland, Congress Poland, and Galicia.

⁷ Figures for 1909-10 to 1918-19 refer to pre-war boundaries; 1914-15 to 1918-19 are exclusively of invaded territory.

⁸ Bohemia, Moravia, and Silesia only.

⁹ Preliminary.

¹⁰ Unofficial estimate.

Bureau of Agricultural Economics. Estimated world total sugar production for the period 1895-96 to 1908-9 in Agriculture Yearbook, 1924, p. 803.

¹ Preliminary.² No sugar produced.³ Includes Turkey in Asia.⁴ The manufacture of beet sugar by the Japan Sugar Co. in Chosen has been discontinued, according to trade reports.⁵ Unofficial estimate.⁶ Exclusive of production in minor producing countries for which no statistics are available.⁷ The figures quoted for India are for the production of gur, a low grade of sugar polarizing between 50° and 60°. Practically the entire crop is consumed within the country.⁸ All grades of sugar reduced to terms of head sugar, a grade of sugar which contains at least 96.5 percent sucrose. Figures for Java are for the calendar years 1922 to 1934.⁹ Unofficial estimate of production of centrifugal sugar, which usually accounts for about 90 percent of the total sugar production.¹⁰ Production in the Philippine Islands is not included in this total as the figures quoted for the last 3 years are not comparable with earlier years.

Bureau of Agricultural Economics; official sources, International Institute of Agriculture and Sugar Associations estimates except as otherwise stated.

Figures are for the crop years 1921-22 to 1933-34 for the countries in which the sugar-harvesting season begins in the fall months and is completed during the following calendar year, except in certain cane-sugar producing countries in the Southern Hemisphere, such as Argentina, Australia, Mauritius, Union of South Africa, etc., where the season begins in May or June and is completed in the same calendar year. Production in these countries is for the calendar years 1921 to 1933.

¹ Beginning with 1919 prices are average prices for crop marketing season.² Compiled from Commerce and Navigation of the United States, 1890-1917; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States, June issues 1919-26, January and June issues, 1927-33, and official records of the Bureau of Foreign and Domestic Commerce.³ Total exports (domestic exports plus foreign) minus imports.⁴ Revised on basis of 1899.⁵ Preliminary.

Bureau of Agricultural Economics.

Italic figures are census returns; other acreage, yield, and production figures are estimates of the Crop Reporting Board, revised, 1919-28. See introductory text. See p. 970, 1927 Yearbook, for data for earlier years.

Estimated world total ¹²	—	—	—	—	—	—	5,168,000	—	—

¹ Acreage and production figures are for the harvesting season. In the Northern Hemisphere, data for 1931-32, for example, are for crops harvested in the summer and fall of 1931; in the Southern Hemisphere they are for crops harvested in the spring of 1932, except in the Dutch East Indies, where the harvest was largely completed in 1931.

² Calculated from actual acreage and production, except in instances where rounded figures only were available.

³ Preliminary.

⁴ Unofficial.

⁵ Exclusive of Northwest Frontier Province.

⁶ Exclusive of Cambodia.

⁷ Exclusive of Cambodia and Tonking.

⁸ Data for European plantations only.

⁹ 1930-31.

¹⁰ Exclusive of Kibondo district, where 15 acres were grown.

¹¹ Exclusive of production in native locations and reserves, which is estimated at 1,000,000 pounds annually.

¹² Exclusive of China. An official estimate of the "average" annual production in 25 of the 28 Provinces in China, issued in 1932, was 465,000,000 pounds. The production of flue-cured tobacco was estimated at 105,000,000 pounds in 1932-33 and between 131,000,000 and 141,000,000 pounds in 1933-34.

Bureau of Agricultural Economics; compiled from official sources, International Institute of Agriculture, and reports of United States consuls, commercial attachés, agricultural attachés, and commodity specialists in foreign countries, except as otherwise stated.

¹ Production and price data, 1919-29, revised May 1932.² Stocks as of July 1 and disappearance beginning July 1.³ Calculated by converting stemmed to unstemmed and storage weight to green, or farmers' sales weight, by allowing for normal losses of moisture and stem.⁴ Type 22.⁵ Type 23.⁶ Stocks as of Jan. 1 of year following production, and disappearance beginning Jan. 1 of year following production.⁷ Previous to 1929 tobacco stocks reports included Pennsylvania and New York. Pennsylvania is believed to refer entirely to type 41. New York is believed to include type 53 produced both in New York and Pennsylvania.⁸ Type 45.⁹ Type 62.¹⁰ Includes primed Havana seed, which has not been reported separately since 1929.¹¹ Type 54.¹² Type 55.¹³ Includes Eastern Ohio and Perique. For years 1920-24 Round Tip also included. The stocks for earlier years probably include some other tobacco not reported separately as to type.¹⁴ Tobacco stock classification changed in 1929, increasing miscellaneous stocks, so that 1928 disappearance cannot be made comparable.

Bureau of Agricultural Economics; stocks prior to 1929 compiled from reports of the Bureau of the Census.

¹ The quantities given are unstemmed equivalent of all kinds of tobacco used. Stemmed leaf and scraps, etc., used in manufacturing have been converted to unstemmed equivalent at the ratio of 3 pounds stemmed to 4 pounds unstemmed; in respect to leaf used in the manufacture of tobacco and snuff, prior to 1928 no conversion factor was used but in this table all figures are compiled on the conversion basis named.

Bureau of Internal Revenue.

1933 7	143,827	77,232	.72	8 82,139	40,044							

¹ Included in "Total crop." By commercial crop is meant that portion of the total crop which is sold for consumption as fresh fruit.

² For years 1920-22, it is assumed that the car lots averaged 600 bushels per car. For years 1923 to 1933, inclusive, the estimates of bushels shipped have been calculated according to estimated loadings in each State.

³ Compiled from Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26; January and June issues, 1927-33; and official records of the Bureau of Foreign and Domestic Commerce.

⁴ Dried and canned are converted to terms of fresh apples on following bases: 1 pound of dried is equivalent to about 5 pounds fresh; 1 pound of canned is equivalent to about 2 pounds fresh; 48 pounds fresh equal 1 bushel. No reexports reported.

⁵ Total exports (domestic plus foreign) minus imports.

⁶ Includes 220,000 bushels not harvested on account of market conditions.

⁷ Preliminary.

⁸ December forecast of total shipments from 1933 crop.

Bureau of Agricultural Economics; production figures are estimates of the Crop Reporting Board, revised, 1919-28.

See introductory text; italic figures are census returns. Prices to producers are based upon returns from crop reporters.

¹ Included in "Total crop." By commercial crop is meant that portion of the total crop which is sold for consumption as fresh fruit.

² Preliminary

³ Average price for 6 months.

⁴ Includes 220,000 bushels not harvested on account of market conditions. Prices are computed on harvested crop.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

¹ Less than 10 quotations.

Bureau of Agricultural Economics; compiled from daily market reports from the Bureau representative at New York.

Average prices as shown are based on stock of good merchantable quality and condition, 2½ inches unless otherwise stated; they are simple averages of daily range of selling prices. Average for season is simple average of monthly averages.

TABLE 176.—*Apricots: Production and average price per ton received by producers, California, 1924-33*

¹ On the late Danish crop, season prices are computed only to Dec. 1.² Season begins in fall of previous year.³ Includes some quantities not harvested on account of market conditions: California, 7,500 tons in 1931; Florida, 7,100 tons in 1931 and 6,500 tons in 1933; Texas, 37,500 tons in 1931; South Carolina, 10,200 tons in 1931; Virginia, Eastern Shore, 1,400 tons and Norfolk section, 5,000 tons in 1931; Ohio (southeast), 2,200 tons in 1931; Colorado, 4,000 tons of domestic and 8,300 tons of Danish in 1932; New York, domestic, 12,000 tons in 1932. Price refers to harvested portion of crop.⁴ Includes quantities used by sauerkraut manufacturers.⁵ Short-time average.⁶ All these figures are included in upper portion of this table but are segregated here for convenient reference.⁷ Other States includes Arkansas, Iowa, Maryland, Missouri, New Jersey, Oregon, Pennsylvania, Tennessee, Utah, and Virginia.

Bureau of Agricultural Economics; estimates based upon returns from crop reporters and sauerkraut manufacturers.

¹ The figures in this table of production included fruit consumed on farms, sold locally, and used for manufacturing purposes, as well as that shipped. The figures do not include fruit which ripened on the trees, but which was destroyed by freezing or storms prior to picking. For California the figures relate to the crop produced from the bloom of the year shown, fruiting through the winter and through the spring and summer of the following year, being picked from Nov. 1 of the year shown to Oct. 31 of the following year. Fruit not picked until after the latter date is included with the crop of the following year. For all States except California the estimates include all fruit picked after about Sept. 1 of the year shown. The estimates for oranges include tangerines.

² From prospects on Dec. 1, commercial shipments of Florida citrus fruits from the 1933 crop were estimated at 13,900,000 boxes of oranges, and 7,000,000 boxes of grapefruit, compared with 15,000,000 boxes of oranges and 8,400,000 boxes of grapefruit shipped from the 1932 crop. Commercial estimates and forecasts include allowance for truck shipments.

³ For years 1919-33, equivalent in standard boxes, each equal to about 2 of the "half straps" commonly used.

⁴ Season average prices, 1919-32; season average price to Dec. 1, 1933. California prices are for naked fruit at the packing-house door; Florida prices are for packed boxes minus selling charges on the commercial crop so handled and bulk prices for other commercial and noncommercial marketings; Florida lime prices, 1919-23, are Dec. 1 prices.

⁵ Census. Size of boxes not specified.

⁶ 500 boxes or less.

⁷ As estimated from prospects on Dec. 1.

Bureau of Agricultural Economics; production figures are estimates of the Crop Reporting Board, revised 1919-28 (see introductory text).

¹ Year beginning July; reports of Bureau of Foreign and Domestic Commerce.

² Cases on basis of 24 No. 2 cans.

³ Preliminary estimate of Florida Grapefruit Cannery Association; there are some cannery outside the association.

Bureau of Agricultural Economics.

Figures on the Florida pack of canned grapefruit were obtained as follows: 1921-22 to 1927-28, averages of various trade estimates; 1928-29, estimated by the Florida Grapefruit Cannery Association; 1929-30 to 1931-32, complete surveys made by the Bureau of Foreign and Domestic Commerce; 1932-33, preliminary report of the pack of the Florida Grapefruit Cannery Association, subject to revision. A box of fresh fruit in Florida is estimated to pack slightly more than a case of canned fruit.

Some grapefruit also is canned in Texas, Arizona, and California. Considerable quantities are exported from the United States, and Puerto Rico also ships to foreign countries.

¹ Prices and value are computed on the harvested crop plus a quantity of fruit that was sold but left on the vines in 1930.

² Preliminary.

³ Includes some quantities not harvested on account of market conditions as follows: Wine varieties, 1928, 18,000 tons; 1930, 40,000 tons; 1932, 25,000 tons; 1933, 3,000 tons; raisin varieties (not dried), 1928, 60,000 tons; 1930, 319,000 tons including 316,000 tons sold but left on the vines; 1932, 21,000 tons; table varieties, 1926, 15,000 tons; 1927, 142,000 tons; 1928, 75,000 tons; 1930, 74,000 tons; 1932, 108,000 tons; 1933, 3,000 tons.

⁴ Dried basis: 1 ton of dried raisins equivalent to 4 tons of fresh grapes.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

Estimates of production for 1929-32 revised on basis of 1930 census. Earlier years not so revised.

¹ For years 1925-28, the average price for the States reporting price, except California, is used for computing the value of the grape crop in the less important States for which no price is determined. Price and value are based on quantities actually harvested plus a quantity of fruit that was sold but left on the vines in 1930.

² Compiled from Monthly Summary of Foreign Commerce of the United States, June issues, 1923-26; January and June issues, 1927-33.

³ Total exports (domestic plus foreign) minus total imports.

⁴ Net import equals total imports minus total exports (domestic plus foreign).

⁵ Less than 0.05 percent.

⁶ Includes fruit in California not harvested as follows: 138,000 tons in 1925, 15,000 tons in 1926, 142,000 tons in 1927, 153,000 tons in 1928, 433,000 tons in 1930 including 316,000 tons sold but left on the vines, 10,000 tons in 1931, 154,000 tons in 1932, and 6,000 tons in 1933. (See also last sentence of note 1.)

⁷ Preliminary.

Bureau of Agricultural Economics; production figures are estimates of the Crop Reporting Board. Prices are based upon returns from crop reporters. Estimates of production for 1929-32 revised on basis of 1930 census. Earlier years not so revised.

¹ Crop-movement season extends from June 1 through December of a given year. Figures for California include shipments in January, February, and March following the regular crop-movement season.

² Preliminary.

Bureau of Agricultural Economics; compiled from daily and monthly reports received by the Bureau from officials and local agents of common carriers throughout the country.

Shipments as shown in car lots include those by boat reduced to car-lot basis. Shipments by truck not included.

¹ Bushels containing approximately 57 pounds.² Includes some quantities not harvested on account of market conditions: early—California, 50,000 bushels in 1932; Texas, 726,000 bushels in 1931, intermediate—California, 204,000 bushels in 1932, late—California, 75,000 bushels in 1930 and 454,000 bushels in 1932; Colorado, 145,000 bushels in 1929 and 174,000 bushels in 1932; Idaho, 170,000 in 1932; Iowa, 10,000 bushels in 1932. Price refers to harvested portion of crop.³ Short-time average.

Bureau of Agricultural Economics; estimates based upon returns from crop reporters.

¹ No quotations for U.S. No. 1 grade; prices shown are for U.S. Commercial grade which is not comparable with U.S. No. 1.

² Car-lot sales.

Bureau of Agricultural Economics; compiled from daily market reports from Bureau representatives in the markets.

Average prices as shown are based on stock of U.S. No. 1 grade, except as otherwise stated; they are simple averages of daily range of selling prices. In some cases conversions have been made from larger to smaller units or vice versa in order to obtain comparability.

1933 ⁷	⁶ 45,326	.76	32,618					

¹ Dried peaches converted to terms of fresh on the basis that dried peaches equal 19 percent of fresh. Canned peaches converted to terms of fresh on the basis that 24 pounds of fresh equal 1 dozen cans of 1 pound each; 48 pounds fresh equals 1 bushel. In practice, 1 bushel of fresh fruit is figured as the equivalent of 2 dozen cans of 1 pound each. No reexports reported.

² From 1919 to 1922, Sept. 15 price; 1923-25, Sept. 15 price in North, Aug. 15 price in South; 1926-33, average price for the crop marketing season.

³ Compiled from Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26, January and June issues, 1927-33.

⁴ Canned peaches were reported in value only, prior to July 1, 1922.

⁵ No exports reported prior to Jan. 1, 1922; figures for 1921 represent exports Jan. 1, 1922, to June 30, 1922.

⁶ Includes fruit not harvested as follows: 1926, 1,462,000 bushels in Georgia and Northern States; 1927, 2,708,000 bushels in California; 1928, 2,917,000 bushels in California and 1,000,000 bushels in Georgia; 1930, 10,648,000 bushels in California including 6,180,000 sold but left on the trees; 1931, 8,063,000 bushels in California including 3,938,000 sold but left on the trees; 1932, 6,710,000 bushels in California; 1933, 3,647,000 bushels in California including 1,480,000 bushels sold but left on the trees. Values are based on the quantity actually harvested plus a quantity of fruit that was sold but left on trees in 1930, 1931, and 1933.

⁷ Preliminary.

Bureau of Agricultural Economics; production figures are estimates of the Crop Reporting Board. Italic figures are census returns. Prices based upon returns from crop reporters. Estimates of production for 1929-32 revised on basis of 1930 census. Earlier years not so revised.

¹ Preliminary.

² Includes some quantities not harvested on account of market conditions as follows: 1926, 1,462,000 bushels in Georgia and Northern States; 1928, 1,000,000 bushels in Georgia; California, 1927, clingstone, 2,708,000 bushels; 1928, clingstone, 2,917,000 bushels; 1930, clingstone, 10,138,000 bushels including 6,180,000 sold but left on the trees, freestone, 500,000 bushels; 1932, clingstone, 6,376,000 bushels, freestone, 334,000 bushels; 1933, clingstone, 3,647,000 bushels, including 1,480,000 sold but left on the trees. Prices and values are computed on the quantity actually harvested plus a quantity of fruit that was sold but left on trees in 1930 and 1933.

³ Mainly for canning.⁴ Mainly for drying.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

Estimates of production for 1929-32 revised on basis of 1930 census. Earlier years not so revised.

¹ Crop-movement season extends from May through October of a given year. Figures for New York for 1924, 1926, and 1932 include shipments in November following the regular crop-movement season.

² Preliminary.

³ No shipments because of frost killing.

Bureau of Agricultural Economics; compiled from daily and monthly reports received by the Bureau from officials and local agents of common carriers throughout the country.

Shipments as shown in car lots include those by boat reduced to car-lot basis. Shipments by truck not included.

¹ From 1919 to 1925, Nov. 15 price; 1926-33, average price for the crop marketing season.

² Canned pears converted to terms of fresh on the basis that 1 pound canned fruit is equivalent to 2 pounds fresh; dried pears converted to terms of fresh on the basis that dried pears equal 25 percent of fresh; 48 pounds fresh equals 1 bushel. No imports of pears reported. Compiled from Monthly Summary of Foreign Commerce of the United States, June issues, 1923-26, January and June issues, 1927-33.

³ Exports were reported in value only, prior to July 1, 1922.

⁴ January-June, 1932. Not previously reported.

* Includes some quantities not harvested on account of market conditions as follows: 1,292,000 bushels in 1929, 625,000 bushels in 1931, 2,666,000 bushels in 1932, and 1,667,000 in 1933. Prices and value are computed on harvested crop.

⁵ Preliminary.

Bureau of Agricultural Economics; production figures are estimates of the Crop Reporting Board. Price figures are census returns. Prices are based upon returns from crop reporters. Estimates of production for 1929-32 revised on basis of 1930 census. Earlier years not so revised.

¹ Beginning with 1919 prices are weighted average prices for crop marketing season.² Compiled from Producers Price Current. Prices 1909-19 are averages of the high and low weekly quotations of New York potatoes, October-June, converted from dollars per 180 pounds to cents per bushel; beginning 1920, season September-May.³ Compiled from Commerce and Navigation of the United States, 1909-17; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26, January and June issues, 1927-33, and official records of the Bureau of Foreign and Domestic Commerce.⁴ The difference between total exports (domestic exports plus reexports) and total imports; + indicates net exports and - indicates net imports.⁵ Preliminary.

Bureau of Agricultural Economics.

Acreage, yield, and production figures are estimates of the Crop Reporting Board, revised, 1919-28. See introductory text; italic figures are census returns. Prices received by producers are based upon returns from crop reporters. See 1927 Yearbook, p. 881, for data for earlier years.

¹ Preliminary.² 4-year average.

Bureau of Agricultural Economics.

Both acreage and production figures refer to the year of harvest. Harvests of the Northern Hemisphere are combined with those of the Southern Hemisphere which immediately follow; thus, for 1933-34 the crop harvested in the Northern Hemisphere countries in 1933 is combined with the Southern Hemisphere harvest which begins late in 1933 and ends early in 1934.

¹ Crop-movement season covers 19 months, from December through the second following June; i.e., the 1923 season begins in December 1922 and ends June 1924.

² Preliminary beginning January 1932.

Bureau of Agricultural Economics: compiled from daily and monthly reports received by the Bureau from officials and local agents of common carriers throughout the country.

Shipments as shown in car lots include those by boat reduced to car-lot basis, 400 to 700 bushels to a car-load. Shipments by truck not included.

¹ Crop-movement season covers 15 months, from October of the preceding year through December of the year shown. Figures for Maryland, Washington, and New Jersey, include shipments in January succeeding the regular crop-movement season.

² Preliminary.

Bureau of Agricultural Economics. Compiled from daily and monthly reports received by the Bureau from officials and local agents of common carriers throughout the country.

Shipments as shown in car lots include those by boat reduced to car-lot basis. Shipments by truck not included.

See footnotes p. 551.

Bureau of Agricultural Economics compiled from daily reports made by common carriers to Bureau representatives in the various markets. Unloads as shown in car lots include boat receipts reduced to car-lot equivalents but exclude truck and i.e.i. express and freight receipts. This table not comparable with table published in former Yearbooks.

STATISTICS OF MISCELLANEOUS CROPS

TABLE 267.—*Beans, dry, edible:*¹ *Acreage, production, value, foreign trade, etc., United States, 1919-33*

Year	Acreage harvested	Average yield per acre	Production	Weighted average price per 100 pounds received by producers ²	Farm value, basis weighted average price ³	Whole-sale price per 100 pounds at Chicago ⁴	Foreign trade, year beginning July	
							Imports ⁵	Domestic exports ⁶
	1,000 acres	Pounds	1,000 bags ⁷	Dollars	1,000 dollars	Dollars	1,000 bushels	1,000 bushels

1932	1,408	741.5	10,440	2.01	20,025	2.46	157	140
1933 ⁸	1,671	734.9	12,280	2.79	32,397			

¹ Table includes, besides the ordinary edible beans and limas, the Blackeye of California which is identical with the blackeyed pea of the South. Soybeans not included.

² Price of cleaned beans.

³ Farm value of dry, edible beans equals the price of cleaned beans applied to the production of cleaned beans rather than total production.

⁴ Prices 1899 and 1909 from Chicago Board of Trade annual reports, quotations for navy, good to choice; 1914-33 from Daily Trade Bulletin, pea beans.

⁵ Imports and exports compiled from Commerce and Navigation of the United States, 1910-17; Foreign Commerce and Navigation of the United States, 1918; Monthly Summary of Foreign Commerce of the United States, June issues, 1919-26; January and June issues, 1927-33; and official records of the Bureau of Foreign and Domestic Commerce.

⁶ Not separately reported prior to 1918.

⁷ Bags of 100 pounds. Computed from bushels of 60 pounds.

⁸ Acreage grown alone.

⁹ Preliminary.

Bureau of Agricultural Economics.

Italic figures are census returns; census figures include all States; other figures, estimates of Crop Reporting Board, principal producing States only, revised, 1919-28. See introductory text.

Estimates of acreage, yield, production, price to producers, and farm value previous to 1919, as published in Yearbook for 1933 and earlier years, are not comparable with the revised series in this table.

TABLE 268.—*Beans, dry, edible:*¹ *Acreage, yield, production, and weighted average price per bag of 100 pounds received by producers, by States, averages, and annual 1932 and 1933*

¹ Table includes, besides the ordinary edible beans and limas, the Blackeye of California, which is identical with the blackeye pea of the South. Soybeans not included.

² The bean classification figures in table 263 of 1932 Yearbook, and similar data in preceding issues, were on a different basis from those in table 258 of 1933 Yearbook and those in the present table. The present grouping has been made upon a classification basis consistent with the United States standards for beans.

³ Preliminary.

⁴ Special California classes.

⁵ Including production of dark red beans in Michigan: 69,000 bags in 1930, 76,000 bags in 1931, 91,000 bags in 1932, and 70,000 bags in 1933.

⁶ Including, in some Western States, seed beans of garden varieties.

Bureau of Agricultural Economics; based upon reports by growers on proportion of total production made up of each variety, supplemented by investigations of field statisticians.

Revised, 1919-23. See introductory text.

¹ Excluding soy, mung, adzuki, broad, and horse beans and similar classes not commonly used as edible beans in the United States.

² Preliminary.

³ Unofficial estimate.

⁴ 4-year average.

⁵ Production in Hokkaido Province, where most of the dry edible bean varieties are grown.

⁶ 3-year average.

Bureau of Agricultural Economics; official sources and International Institute of Agriculture except as otherwise stated.

Figures are for the harvesting seasons 1921 to 1933 in the Northern Hemisphere and 1921-22 to 1933-34 in the Southern Hemisphere.

¹ Crop-movement season extends from September of one year through August of the following year.

² Preliminary.

³ In addition to rail shipments, 190,267 bags were shipped by river boats or barges.

Bureau of Agricultural Economics; compiled from monthly reports received by the Bureau from local agents of common carriers throughout the country.

Shipments as shown in car lots include those by boat reduced to car-lot basis. Shipments by truck not included. Beginning 1932-33, shipments are reported in bags of 100 pounds each and the data include all shipments originating at shipping points whether in car lots or less than car lots. The figures therefore are not comparable with those in other years, which are for car-lot shipments only.

¹ Soybeans planted in corn in Northern States not included. For Southern States such acreage is included reduced to its equivalent solid acreage.

² Solid equivalent of acres from which the soybeans were gathered.

³ The large acreage and production of soybeans grazed or hogged off in the Southern States are included in these figures, but the small acreage and production of soybeans thus harvested in the North are not included.

⁴ Preliminary.

⁵ Average price for 3 months.

⁶ Average of State prices for gathered beans weighted by total equivalent production for all purposes.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

¹ Preliminary.² These figures are for yellow soybeans, which variety constitutes fully 98 percent of the soybean exports.³ 3-year average.⁴ Imports for consumption.⁵ Domestic exports of soybeans are not separately reported in Foreign Commerce and Navigation of the United States; if any, included with exports of "oilseeds." Soybeans inspected for export began in October 1931, there being 7,978,800 pounds exported from October to December; inspected for export calendar year 1932, 262,345,480 pounds.⁶ International Yearbook of Agricultural Statistics.⁷ 4-year average.

Bureau of Agricultural Economics; official sources except where otherwise noted.

¹ Average for months quoted.² Domestic oil not quoted prior to October 1929, as production in this country had not reached commercial proportions.

Bureau of Agricultural Economics. Compiled from the Oil, Paint, and Drug Reporter. Prices are average of quotations on Saturdays during the month.

Through August 1911, quotations are for English, spot; September 1911-April 1916, English or Manchuria; May 1916-January 1919, Manchuria only; February 1919, and subsequently, origin not indicated. Quotations for imported do not appear after April 1932, as importations had practically ceased as a result of a prohibitive tariff.

¹ Cowpeas planted in corn in Northern States not included. For Southern States such acreage is included reduced to its equivalent solid acreage.

² Solid equivalent of acres from which the cowpeas were gathered.

³ Preliminary.

⁴ The large acreage and production of cowpeas grazed or hogged off in the Southern States are included in these figures, but the small acreage and production of cowpeas thus harvested in the North are not included.

⁵ Average price for 5 months.

⁶ Average of State prices for gathered peas weighted by total equivalent production for all purposes.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

Bureau of Agricultural Economics. Based on returns from special-price reporters. Monthly prices, by States, weighted by production to obtain a price for the United States; yearly price obtained by weighting monthly prices by monthly marketings. For previous data on alfalfa, clover, timothy, and prairie hay see 1930 or earlier Yearbooks.

TABLE 290.—*Hay, tame, by kinds: Production, United States, 1919-33*

Bureau of Agricultural Economics. Based on returns from special price reporters. Monthly prices, by States, weighted by production to obtain a price for the United States; yearly prices obtained by weighting monthly prices by average monthly marketings. For previous data see 1930 or earlier Yearbooks.

¹ Figures for 1900–1919 are tentative revised estimates of the Bureau of Agricultural Economics.

² Obtained by subtracting the estimates of "milk cows on farms" shown in table 378 from the estimates of "all cattle on farms" shown in this table.

³ Data for 1900–1925 are an old series adjusted on basis average relationship between the old and new series for 1926–28. Old series was weighted averages of prices by age groups only and was shown in 1928 Yearbook. The conversion factor was 0.9466 (base is old series). Data for 1926–34 are a new series, referred to above, of average values by age and sex classification, weighted by numbers in each class.

⁴ Italic figures are from the census. 1900, 1910, and 1930 include spring-born calves. Census dates were June 1, 1900; Apr. 15, 1910; Jan. 1, 1920 and 1925; Apr. 1, 1930.

⁵ Preliminary.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

¹ Sum of total value of subgroups (classified by age and sex) divided by total number and rounded to nearest dime for States. Division and United States averages not rounded. State figures are new weighted value series, not comparable to State figures previously published for the years prior to 1925.

² Preliminary.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

To 1932 (40) ²⁰		249,662	256,423	259,154	246,681	244,040	241,804
Estimated world total including Russia. ^{8 21}		641,900	670,800				

¹ Average for 5-year period if available, otherwise for any year or years within this period except as otherwise stated.

² Incomplete.

³ Average of 1926 estimate for 96 percent municipalities and 1930 census

⁴ Census.

⁵ Year 1918.

⁶ Unofficial.

⁷ Countries reporting as of December have been considered as of Jan. 1 of following year.

⁸ These totals include interpolations for a few countries not reporting each year and rough estimates for some others.

⁹ Buffaloes included.

¹⁰ Year 1920.

¹¹ Census June.

¹² In rural communities only.

¹³ Preliminary census figures for May 27.

¹⁴ Estimate of total number based on number in rural communities only as compared with preceding year.

¹⁵ November.

¹⁶ Estimated by Basutoland Government agricultural official on the presumption that previous estimates are too high.

¹⁷ Included unofficial estimate of 690,000 buffaloes.

¹⁸ Estimate based on official figures in 1920 for 20 Provinces, which supported 63 percent of the cattle in China in 1914. No data available in 1920 for such important Provinces as Hupeh with 1,898,000 in 1914, Hunan with 2,192,000, Szechuan with 3,009,114, Kwantung with 2,288,000, and Kwangsi with 1,527,000.

¹⁹ Estimate based on official figures in 1932 or 1933 for 22 Provinces, which supported 97 percent of the cattle in China in 1914. The official estimate excluding Turkistan, and Inner Mongolia for 1932 or 1933 was 22,333,000. Estimates for this territory and for Manchuria included with China, although some of it has recently been incorporated into Manchukuo.

²⁰ Comparable totals for number of countries indicated.

²¹ Estimated totals for continents are as follows in millions of head for the 5-year average, 1909-13: North America, Central America, and West Indies, 71.9; South America, 80.3; Europe, excluding Russia, 103.3; Africa, 33.8; Asia, excluding Russia, 195.3; Oceania, 13.8; world including Russia, 562.

Bureau of Agricultural Economics: compiled from reports of United States Government representatives abroad, original official sources, and the International Institute of Agriculture unless otherwise stated.

Figures in parentheses interpolated. For later figures for individual countries see Cattle and Beef issue of Foreign Crops and Markets.

Bureau of Agricultural Economics. Compiled from Review of the River Plate, as follows: 1924-27, average of Thursday quotations; 1928-33, average of high and low for weeks ended Saturday. Prior to May 1924, originally quoted on basis of price per head supplemented by price per pound of dressed carcass weight. Calculations assume average dressed weight of 730 pounds or live weight of 1,259 pounds. Beginning May 1924, prices were quoted in live weight per pound. Converted at average monthly rates of exchange as given in Federal Reserve Bulletin.

Bureau of Agricultural Economics. Estimates of Division of Crop and Livestock Estimates and are preliminary. The figures on income as shown in tables 439 and 460 are computed from the data shown in this table. The difference between gross income and value of production arises from the fact that in computing value of production allowance is made for changes in inventory numbers between the beginning and end of the year, while in computing incomes these changes are not used.

1933 ⁵	13,562	(⁶)	2,527	-----	(⁴)	-----

¹ Including municipal and private slaughterhouses, the figures were as follows, in thousands: 1929, 6,138; 1930, 5,966; 1931, 5,383. The numbers killed in freezing and chilling plants alone were as follows, in thousands: 1929, 2,792; 1930, 2,679; 1931, 2,297; 1932, 2,214; 1933, 2,350.

² Slaughtering in freezing and chilling plants alone was as follows, in thousands: 1929, 853; 1930, 1,108; 1931, 901; 1932, 754; 1933, 816.

³ For years beginning Apr. 1.

⁴ Slaughter for export only was as follows in thousands: 1929, 471; 1930, 429; 1931, 425; 1932, 397.

⁵ Preliminary estimate.

⁶ Inspected slaughter, only, was as follows in thousands: 1929, 1,117; 1930, 978; 1931, 963; 1932, 937; 1933, 1,092.

Bureau of Agricultural Economics; compiled from official sources and cabled reports from agricultural representatives abroad.

¹ Figures for 1900–1919 are tentative revised estimates of the Bureau of Agricultural Economics.² Data for 1900–1925 are an old series for all hogs as reported, adjusted on basis average relationship between the new and the old series for 1926–28. Old series was shown in 1928 Yearbook. Conversion factor was 1.057 (base was old series). Data for 1926–34 are a new series, referred to above, of average values by age and sex classification weighted by numbers in each class.³ Italic figures are from the census. Census dates were June 1, 1900; Apr. 15, 1910; Jan. 1, 1920 and 1925, Apr. 1, 1930. 1900, 1910, and 1930 include spring-born pigs.⁴ Preliminary.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

To 1931 (35) ¹⁰		144,000	150,835	152,178	143,455	152,134	
To 1932 (27) ¹⁰		137,360	143,777	144,648	135,867	144,392	144,612
Estimated world total including Russia. ^{4 17}		254,800	280,140				

¹ Average for 5-year period if available, otherwise for any year or years within that period unless otherwise stated.

² Incomplete.

³ Census.

⁴ These totals include interpolations for a few countries not reporting each year and rough estimates for some others.

⁵ Year 1920.

⁶ Unofficial.

⁷ Estimates of countries reporting as of December are considered as of Jan. 1 of following year, i.e. the figures for the number of hogs in France as of Dec. 31, 1928, have been placed in 1929 column, etc.

⁸ June.

⁹ Rural communities only.

¹⁰ June 20.

¹¹ May.

¹² Year 1925.

¹³ November.

¹⁴ Estimate based on official figures for 1920 for 20 Provinces which supported over 50 percent of the number in China in 1914.

¹⁵ Estimate based on official figures for 1932 or 1933 for 22 Provinces which supported over 99 percent of the number in China in 1914. The official estimate excluding Turkistan and Inner Mongolia in 1932 or 1933 was 94,395,000. Estimates for this territory and for Manchuria included with China, although some of it has recently been incorporated into Manchukuo.

¹⁶ Comparable total for number of countries indicated in parenthesis.

¹⁷ Estimated world production for the 5 years 1909-13 was as follows in thousands of head: North America, Central America, and West Indies, 62,500; South America, 23,500; Europe, excluding Russia, 71,800; Africa, 2,500; Asia, excluding Russia, 85,900; Oceania, 1,300; world including Russia, 267,500.

Bureau of Agricultural Economics; official estimates and International Institute of Agriculture unless otherwise stated.

Figures in parenthesis interpolated. For later figures see the Hog and Pork Issue of Foreign Crops and Markets and the monthly issues of Hog and Pork Prospects.

Bureau of Agricultural Economics. Compiled from reports of packer and shipper purchases; such purchases do not include pigs, boars, stags, extremely rough sows, or cripples. The yearly figures are the simple average of the October to September prices. Data for 1901-23 are available in 1932 Yearbook, p. 789, table 336.

TABLE 339.—*Hogs: Annual slaughter under Federal inspection, 1907-33, estimated equivalent of Federal inspection, 1900-1906, and estimated total slaughter (including farm) in United States, 1900-1933¹*

Bureau of Agricultural Economics. Estimates of Division of Crop and Livestock Estimates and are preliminary. The figures on income as shown in tables 459 and 460 are computed from the data shown in the table. The difference between gross income and value of production arises from the fact that in computing value of production allowance is made for changes in inventory numbers at the beginning and end of the year, while in computing income these changes are not used.

¹ Average for 5-year period if available; otherwise, for any year or years within this period except as otherwise stated.

² Incomplete.

³ Census figures.

⁴ These totals include countries with less than 100,000; interpolations for a few countries not reporting each year and rough estimates for some others.

⁵ Unofficial.

⁶ Estimates for countries reporting as of Dec. 31 have been considered as of Jan. 1 of following year; i.e., figures for numbers of sheep in France as of Dec. 31, 1928 have been placed in 1929 column, etc.

⁷ Census 1920.

⁸ June 1930.

⁹ In rural communities only.

¹⁰ May.

¹¹ Years 1921-28 from Livestock Industry in the Soviet Union. Later figures from Pravda, Jan. 28, 1934. Sheep numbers for 1929-33 estimated from total number of sheep and goats.

¹² Goats included.

¹³ Estimate based on change in sheep numbers in June compared with preceding June.

¹⁴ Estimate based on official figures for 1929 for 20 Provinces which supported 80 percent of total number in China in 1914.

¹⁵ Estimate based on official estimate for 1932 or 1933 published in the Chinese Economic Bulletin for 22 Provinces which supported 77 percent of total in 1914. The official estimate excluding Turkistan and Inner Mongolia for 1932 or 1933 was 19,995,000. Estimates for this territory and for Manchuria included with China, although some of it has recently been incorporated into Manchukuo.

¹⁶ Comparable totals for numbers of countries indicated.

¹⁷ Comparable estimated world totals by countries were as follows in millions of head: 1909-13, North America, Central America, and West Indies, 49.6; South America, 93.2; Europe (excluding Russia), 134.4; Africa, 71.2; Asia (excluding Russia), 115.3; Oceania, 111.7; Estimated world total, including, Russia, 691.6.

Bureau of Agricultural Economics; compiled from official sources and the International Institute of Agriculture unless otherwise stated.

Figures in parenthesis are interpolated. See Wool issue of Foreign Crops and Markets usually published in May, and World Wool Prospects published monthly by this Bureau, for later figures.

Bureau of Agricultural Economics. Estimates of Division of Crop and Livestock Estimates and are preliminary. The figures on income as shown in tables 459 and 460 are computed from the data shown in this table. The difference between value of production and income arises from the fact that in computing value of production, allowance is made for changes in inventory numbers between the beginning and end of the year, while in computing income these changes are not used.

¹ Preliminary.² Revision of Nov. 10 made at a conference between the presidents of the National Council of Wool Selling Brokers and National Council of Wool Growers of Australia after all selling centers had carefully reviewed their figures. Subject to still further revision if conditions warrant it.³ Estimates based on exports alone or exports, stocks, and domestic consumption and any other available information.⁴ Years 1924 to 1927 supplied by the Empire Marketing Board. Years 1927-28 to 1931-32 official Yearbook of New Zealand 1933 and Monthly Abstract of New Zealand Statistics, August 1933. The estimates of Dalgety & Co. used formerly are as follows in millions of pounds, with scoured wool included at its scoured weight: Average 1923-27, 210.0; 1928, 239.0; 1929, 241.8; 1930, 265.7; 1931, 265.5; 1932, 305.5.⁵ Estimates based on sheep numbers at date nearest shearing and other available data.⁶ Estimates of the Buenos Aires branch of the First National Bank of Boston, based on exports, stocks, and domestic consumption.⁷ Estimates supplied by Assistant Agricultural Commissioner C. L. Luedtke.⁸ Estimates of C. C. Taylor, formerly United States agricultural attaché in South Africa.⁹ Tentative official revision of original estimate.¹⁰ Published as reported by pulleries and is mostly washed. The U.S. Bureau of the Census considers 1 pound of pulled wool the equivalent of 1½ pounds of grease.¹¹ Estimates of the Empire Marketing Board.¹² Revisions based on recent census figures of wool production or of sheep numbers.¹³ Yield estimated to be considerably below 1932, according to Trade Commissioner Elizabeth Humes.¹⁴ Estimates for Asiatic countries rough approximations only.¹⁵ Totals subject to revision. Few countries publish official estimates of wool production. In the absence of official figures for many countries various estimates have been used. Some have been furnished by United States Government representatives abroad and others have been based on reports of sheep numbers, average fleece weights, and any other available data. For some principal exporting countries the figures are seasonal exports alone, or estimates derived from exports, carry-over, and domestic consumption. In the case of most Asiatic countries the figures are rough commercial estimates.¹⁶ Estimate based on production in 34 countries as compared with 1931.¹⁷ Estimate based on sheep numbers and average yield as derived from official estimates for recent years. The Union Soviet Socialist Republics program called for 353,000,000 pounds in 1931 according to the Economic Handbook of the Soviet Union, but this estimate appears much too large considering the decrease in sheep numbers since 1929.¹⁸ Exports of sheep's wool only.

Bureau of Agricultural Economics.

This table includes wool shorn during the calendar year in the Northern Hemisphere and that shorn during the season beginning July 1 or October of the given calendar year in the Southern Hemisphere, the bulk being shorn during the last 6 months of the given calendar year. Pulled wool is included in the total for most important countries at its grease equivalent. Figures in parenthesis are interpolated. See Foreign Crops and Markets annual wool review in May or June 1934 for table showing all countries and monthly World Wool Prospects for current revisions.

¹ Include fleeces taken at commercial feeding plants. California figures include some fleeces taken from early lambs.

² In States where sheep are shorn twice a year, principally Texas and California, this figure covers wool per head of sheep shorn and not weight per fleece.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

Bureau of Agriculture Economics. These data were obtained from prices given by Kreglinger & Fernald for the opening and closing of each series of the London wool sales. For months when no sales were held the figures are interpolations of nearest actual prices. Conversions at monthly average rate of exchange as given in Federal Reserve Bulletins to December 1925, and October 1931 to December 1933; others at par.

TABLE 368.—*Goats and mohair: Estimates of goats clipped, mohair produced, and average clip per goat (principal producing States), 1931-33*

¹ Prior to 1900, estimates for each 10-year period represent an index of annual changes applied to the census as a base on first report after census data were available. Figures for 1900 to 1919 are tentatively revised estimates of the Bureau of Agricultural Economics for numbers on Jan. 1. Figures from 1920 to 1931 are revised estimates made in 1932, based upon study of 1930 census report. Figures for 1900-1934 relate to "cows and heifers 2 years old and over Jan. 1, kept for milk."

² Values for 1880-99 relate to "milk cows." Data for 1900-1925 are an old series of values of "milk cows" adjusted to relate to "milk cows and heifers, 2 years old and over" on basis of relationship between the 2 series from 1926 to 1928. Conversion factor was 0.955 (base is old series). Data for 1926-34 are values relating to "milk cows and heifers 2 years old and over."

³ Italic figures are from the census. Figures for census years 1880 and 1899 represent "milk cows"; 1900, "cows kept for milk 2 years and over"; 1910 "cows and heifers kept for milk, born before Jan. 1, 1909" (15½ months and over); 1920 "dairy cattle 2 years old and over kept mainly for milk production"; 1925 and 1930, "number of cows milked in 1924 and 1929." Census dates were June 1 from 1880 to 1900; Apr. 15, 1910; Jan. 1, 1920 and 1925; Apr. 1, 1930.

⁴ Preliminary.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

¹ Modified accredited counties are those in which tuberculosis does not exist among more than one half of 1 percent of the cattle, as determined by official tuberculin testing, and from which all reactors to the test have been removed.² The figures in these columns represent net increases at the close of each year.³ Represents decrease from figures for previous year.

Bureau of Animal Industry.

Current data on tuberculosis-eradication work, including progress by States and counties, may be obtained from Bureau of Animal Industry.

¹ Estimated average number of milk cows on farms during 1933. The estimates exclude heifers not yet fresh but include some cows which had calves running with them much of the year.

² These estimates exclude milk sucked by calves, milk spilled or lost up to the time it is measured, skimmed, or delivered by farmers, and milk produced by cows not on farms.

³ Approximations based chiefly on the population in small towns and rural areas where most families purchase their milk supply directly from local farmers. Estimates include milk equivalent of cream.

⁴ Estimates include milk delivered to creameries, condensaries, cheese factories, and market-milk receiving stations, but exclude market milk sold to other farmers for local retail delivery.

⁵ As computed by counties.

Bureau of Agricultural Economics; estimates of Division of Crop and Livestock Estimates.

¹ Includes both farm- and factory-made butter. These estimates include some butter used in other products such as ice cream.² Includes all kinds of cheese except cottage, pot, and bakers.³ Includes some condensed and evaporated milk used in other products, also includes both whole- and skim-milk product.⁴ Milk and the milk equivalent of cream consumed per capita by that part of the population not on rural farms. These estimates include some milk and cream used in such products as ice cream and supersede estimates previously issued.⁵ Based on estimates of milk production on farms and elsewhere, with milk fed to calves deducted in calculating per capita consumption.⁶ Preliminary.

Bureau of Agricultural Economics.

Consumption of butter, cheese, evaporated milk, condensed milk, and milk equivalent of all dairy products is calculated from production, foreign trade, and domestic stocks. Milk used in cities and villages is calculated from board of health reports.

¹Included in creamery butter.²Unsweetened condensed milk (plain condensed) was classified as "Evaporated milk (unsweetened), bulk goods", in previous years.³Production in commercial ice-cream factories only.

Bureau of Agricultural Economics, compiled from reports of factories made direct to the Bureau.

Figures beginning with the year 1929 are the most complete since these reports were inaugurated in 1918. Some allowance, therefore, should be made for this when comparing production since 1929 with that of previous years.

Bureau of Agricultural Economics. Quotations include some purchases other than for the manufacture of butter. Based on reports of special price reporters. Monthly prices, by States, weighted by number of milk cows Jan. 1, to obtain a price for the United States; yearly price obtained by weighting monthly prices by production of creamery butter.

Bureau of Agricultural Economics. Compiled from reports of factories made direct to the Bureau. Figures beginning with the year 1929 are the most complete since these reports were inaugurated in 1918. Some allowance, therefore, should be made for this when comparing production since 1929 with that of previous years.

Bureau of Agricultural Economics. Compiled from Danish Butter Journal (Smør Tidende) official quotations in kroner per 100 kilograms, as based each Thursday by 2 committees, representing dairy and commercial interests respectively. For earlier years 1882-1923 see the U.S. Department of Agriculture Yearbook, 1923, and subsequent issues. Converted at monthly average rates of exchange as given in Federal Reserve Bulletin, except for period January 1927-August 1931, when per of exchange was used.

Bureau of Agricultural Economics. Compiled from reports of factories made direct to the Bureau. Figures beginning with the year 1929 are the most complete since these reports were inaugurated in 1918. Some allowances, therefore, should be made for this when comparing production since 1929 with that of previous years.

¹ Quantities given are net weight.

The term "American cheese" is intended to cover only those varieties known as twins, flats, daisies, Cheddars, longhorns, and square prints. It does not, therefore, include all kinds of cheese made in America.

Bureau of Agricultural Economics; compiled from reports made by cold-storage establishments.

Changes in these tables made due to transference of current trading stocks to cold-storage stocks from Jan. 1, 1927, to Dec. 1, 1931.

¹ Does not include forest products, but includes rubber now mostly a plantation product.

² Excess of exports.

³ Excess of agricultural imports.

⁴ Preliminary.

Bureau of Agricultural Economics.

This table supersedes table 500 in the Yearbook of Agriculture, 1931; the value of total imports and exports has been given and the imports of rubber, unmanufactured, and similar gums have been deducted from the imports of forest products and added to imports of agricultural products, also reexports of rubber, unmanufactured, and similar gums have been deducted from reexports of forest products and added to reexports of agricultural products. Rubber, unmanufactured, and similar gums, includes: Balata, gualule, gutta-joolatong or jelutong or pontianak, gutta-percha, India rubber, crude, and India rubber scrap or refuse, fit only for remanufacture.

In the statistics of foreign commerce of the United States the Philippine Islands are treated as a foreign country. The statistics of foreign commerce include the trade of the customs districts of Alaska, Hawaii, and Puerto Rico with foreign countries, but do not include the trade of these Territories with the United States.

Bureau of Agricultural Economics. Computations are based on the gross exports of 44 of the most important farm products. The index numbers were calculated as follows: Quantities of various commodities exported each year were multiplied by the average yearly export prices of these commodities from July 1909 to June 1914. The sum of the values determined in this way was then divided by the average yearly value of exports from 1909-10 to 1913-14 to obtain the index.

TABLE 444.—*Exports and imports of selected forest products, 1909-10 to 1932-33*

Year beginning July	Domestic exports					Imports				
	Lumber		Rosin	Spirits or tur- pen- tine	Tim- ber, sawed	Cam- phor, crude	Lumber		Shellac	Wood pulp

² Preliminary.³ Includes barley flour 1919-22. Barley flour not separately reported prior to 1919 nor since 1922.⁴ Includes "Stems, trimmings, and scrap tobacco."¹⁰ Included with "Starch" prior to 1917-18.¹¹ Given in value only prior to 1922-23.¹² Jan. 1 to June 30.

Bureau of Agricultural Economics; compiled from Foreign Commerce and Navigation of the United States, 1909-18, and Monthly Summary of Foreign Commerce of the United States, June issues 1919-33.

Conversion factors used: Corn meal, 1 barrel=4 bushels corn; oatmeal, 18 pounds=1 bushel oats; rye flour, 1 barrel=6 bushels rye; malt, 1.1 bushels=1 bushel barley; wheat flour, 1 barrel=1909-17, 4.7 bushels grain; 1918 and 1919, 4.5 bushels; 1920, 4.6 bushels; 1921-33, 4.7 bushels; apples, 3 boxes=1 barrel. The unit "1,000 pounds" in the columns of canned goods is presumed to be net weight, according to Government regulations.

¹ Imports for consumption. (See introduction to Agricultural Statistics.)

² Not separately reported prior to 1914-15; 1914-15 to 1917-18 and 1927-28 are imports for consumption; 1918-19 to 1926-27 not available; 1928-29 to 1932-33 are general imports.

³ Includes peanut oil.

⁴ Included in all other fixed or expressed.

⁵ Included in tung oil.

⁶ Includes hempseed.

⁷ Less than 500 pounds.

⁸ Preliminary.

Bureau of Agricultural Economics; compiled from Foreign Commerce and Navigation of the United States, 1910-18; Monthly Summary of Foreign Commerce of the United States, June issues, 1919-33.

¹ Pounds.

² For hay and forage, but not included in tame hay.

³ Bushels of 25 pounds.

⁴ Bag of 100 pounds.

⁵ Includes the acreage, production, and value of that part of the crop gathered, grazed, or hogged off in the Southern States, but acreage cut green and value of vines cut or saved for hay not included.

⁶ Includes some quantities not harvested.

⁷ Production is the total for fresh fruit, juice, and raisins.

⁸ Trees tapped.

⁹ Total equivalent sugar per tree.

TABLE 456.—*Crop summary: Acreage, yield per acre, and production, 1931-33—Continued*

Crop	Acreage harvested			Yield per acre			Unit	Production

1932	76	106	137	104	125	116	104	104
1933	56	106	134	109	126	118	103	100

¹ These indexes are based on estimates of production for sale and for consumption in the farm home. Production fed to livestock or used for seed is not included. For example, instead of total production, only the amounts of corn and oats shipped out of county where grown and only a small percentage of the hay crops are included. The index of dairy products represents total milk production for all purposes. Production of meat animals is represented by total slaughter, including slaughter for farm use. Calendar-year production of livestock and livestock products are here compared with crop production of the same year. Each group index as well as the total is obtained by multiplying the yearly quantities by a 1919-27 average farm price received by producers for each of the commodities, and the sum of these yearly values at average prices, divided by the corresponding average sum for the period 1919-27, taken as 100. The following commodities included in the index contribute about 90 percent of the gross income from agricultural production: Grains—wheat, corn, oats, barley, rye, buckwheat, kafir, rice; fruits and vegetables—grapes, apples, apricots, peaches, pears, cranberries, figs, grapefruit, lemons, olives, oranges, potatoes, sweetpotatoes, dry edible beans; truck crops—parsnips, snap beans, cabbages, cantaloupes, cauliflower, celery, cucumbers, lettuce, onions, peas, spinach, strawberries, tomatoes, watermelons; meat animals—cattle, calves, sheep, lambs, hogs; dairy products—milk total production; poultry products—chickens and eggs, cotton and cottonseed; total includes also tobacco, wool, and hay.

¹ Includes corn (all), oats, barley, grain sorghum (all), wheat (all), rye, buckwheat, flaxseed, rice, beans (dry edible), soybeans alone, cowpeas alone, peanuts alone, velvetbeans alone, tame hay (all), wild hay, sorgo for forage and hay, timothy seed, red and alsike clover seed, sweetclover seed, lespedeza seed, alfalfa seed, cotton, tobacco, sorgo sirup, sugar cane (all), sugar beets, broomcorn, potatoes, sweetpotatoes, asparagus, snap beans, cabbage, cantaloupes, watermelons; farm value also includes apples (all), peaches, pears, onions, green peas, spinach, tomatoes, cherries, pecans, grapefruit, lemons, limes, apricots, plums, prunes (all), figs, olives, almonds, walnuts, maple products.

² Based on price received by producers Dec. 1, except for some early marketed crops for which price for marketing season is used, and differs from prices used in tables 459 and 460.

³ Differs from total in table 456 in that cranberries, hops, artichokes, beets, carrots, eggplant, kale, lima beans, peppers, pimientos, sweet corn (for market), and strawberries are excluded, and for annual legumes only acreage grown alone is included.

Bureau of Agricultural Economics; estimates of the Crop Reporting Board.

TABLE 459.—Gross income from farm production, by States, 1930-32

¹Preliminary.

Bureau of Agricultural Economics. Estimated quantities produced, sold, and consumed in farm households times weighted annual prices. Cash income plus value of commodities consumed in farm households equals gross incomes. For feed and seed crops, horses, and mules, value includes sales by farmers in some States eventually bought by farmers in other States. These interfarm sales tend to overestimate the total income from farm production for the country as a whole.

TABLE 461.—*Gross income from farm production by groups of commodities, expenditures, income available for operators' capital, labor, and management and current value of capital employed in agriculture, United States, 1924-32*

¹ Estimates since 1929 have been adjusted to the revised estimates of production which were made after the 1930 census data became available. Estimates of income from 1924-28 have not yet been adjusted to revised production estimates. The 1929 estimate of income from crops, comparable with the estimates of 1924-28, was \$5,609,000,000 and 1929 estimate of livestock was \$6,302,000,000; total gross income on old base for 1929 was \$11,950,000,000 compared with \$11,911,000,000 when revised.

² All of the current operating costs except 7.5 percent of fertilizer costs, 9.5 percent of feed, 10 percent of binder twine, and 15 percent of ginning costs which are estimated as paid by nonfarmer landlords.

³ Depreciation on buildings, estimated at 5 percent of the values of farm buildings, of farm operators exclusive of dwellings, and 21 percent of the value of farm machinery, automobiles and trucks used for production.

⁴ Cash wages to hired labor plus an allowance of 25 percent for board and an additional 12½ percent of the cash wage to represent perquisites furnished hired labor and domestic hired labor contributing to production. Includes only that portion of interest payable by farm operators; figured at 75 percent of all interest payable on farm mortgage debt on real estate used in production and interest on all bank loans, other than real estate loans. It is assumed that 70 percent of all taxes on farm property used in production are paid by farm operators and that 72 percent of all rent paid is paid to nonfarmer landlords, the remaining 28 percent being paid to farmer operators owning other farms. Rent payable to nonfarmer landlords in 1932 was \$570,000,000.

Bureau of Agricultural Economics.

1932 ¹¹	43,316	5,143	472	359	96	98	441	56	529	486

¹ As of Jan. 1. Includes land, buildings, machinery and livestock. Interpolation between census estimates: Land and buildings based on index of land values per acre and straight line interpolation of total acreage in farms; livestock, annual estimates U.S. Department of Agriculture; machinery, interpolated on basis of estimated values of land and buildings, 1909-19, straight line interpolations, 1920-24 and 1925-30.

² 1924-32, table 461; 1909-23 based on items which represent 95 percent of gross income in 1924-32.

³ Interpolations between census estimates, based on U.S. Department of Agriculture index of farm wages.

⁴ Interpolation between census years based on an index of prices paid by farmers for feed and an index of production of feed crops. The product of the 2 indexes was adjusted to equal the census values of feed purchased.

⁵ Interpolated between census estimates, based on index of value derived from total fertilizer consumption and U.S. Department of Agriculture index of fertilizer prices paid by farmers.

⁶ 1909-19: 1909, 1914, and 1919 census values of farm implements produced adjusted to represent total farm equipment sold in the United States at farm values. Interpolations for other years to 1920 based on gross income from farm production. 1920-30 estimates based largely on factory value of farm implements sold in the United States raised to represent farm values.

⁷ Includes estimated cost of operating automobiles, trucks, and tractors; 50 percent of annual farm purchases of autos and trucks.

⁸ Annual cotton production, multiplied by ginning costs per bale.

⁹ Revised estimates of taxes are based upon study of real estate tax rates by States. Adjustment is made for personal property taxes. Real estate tax is 85 percent and personal property is 15 percent of total.

¹⁰ Interpolations between total farm mortgages for 1910, 1920, 1925, 1928, 1930, using smoothed estimates for 1911-19 derived from value of current agricultural capital, and smooth curve, 1920-30.

¹¹ Preliminary.

Bureau of Agricultural Economics; tentative estimates of the Bureau.

TABLE 463.—Total population and farm population, United States: Total number Apr. 15, 1910, and yearly Jan. 1, 1920-34, annual movement to and from farms, and annual net change in the farm population 1920-33 ¹

¹ Includes charges for water for irrigation, twine and sacks, crop insurance, use of implements, use of storage buildings, overhead, and a charge for expenses incurred on wheat acreages abandoned and not harvested.

² Includes the western portion of the northern Great Plains extending northward from western South Dakota into Montana and including a small portion of southwestern North Dakota, and a portion of northeastern Wyoming. A subhumid climate prevails.

³ Includes the eastern portion of the northern Great Plains, including the Red River Valley in both South Dakota and Minnesota and extending northward from eastern South Dakota into North Dakota and northeastern Montana. A subhumid climate prevails.

⁴ Includes Minnesota east of the Red River Valley, with Wisconsin and that part of Michigan lying north of the 2 southern tiers of counties. In Michigan soft red winter and white wheats prevail over the hard red spring wheat. A dairy type of farm prevails.

⁵ Includes the western portion of the central Great Plains, including the panhandles of Texas and Oklahoma, the plains of eastern Colorado and western Kansas, eastern Wyoming, and western Nebraska. A subhumid climate prevails.

⁶ Includes the eastern portion of the central Great Plains, including a small area in north-central Texas, and a broad band through central Oklahoma, central Kansas, and into Nebraska. A subhumid climate prevails.

⁷ Includes Missouri from the tier of counties just north of the Missouri River south to the State line with adjacent parts of eastern Kansas, northeastern Oklahoma, and southwestern Illinois. A humid climate prevails.

⁸ Includes the region of heavy corn production in Iowa, southeastern South Dakota, eastern Nebraska, southwestern Minnesota, northeastern Kansas, northern Missouri, northern Illinois, northern Indiana, western Ohio, and the 2 southern tiers of counties in Michigan.

^a Includes the area of the Appalachian highland, including Kentucky, Virginia, West Virginia, and extending into southeastern Illinois, southern Indiana, eastern Ohio, with all of Pennsylvania, Maryland, Delaware, New Jersey, New York, and the very limited wheat acreage of the New England States.

^b Includes the States of Tennessee, North Carolina, South Carolina, Georgia, and Alabama.

^c Includes Arkansas, most of eastern Oklahoma, and Texas, with the exception of the panhandle, and the 12 counties included in the eastern Great Plains area.

^d Includes the western portions of Montana, Wyoming, and Colorado, and the other States lying westward to the Pacific coast.

Bureau of Agricultural Economics.

Subject to revision. In computing averages, data were weighted by acreage harvested.

¹ 1912-14=100.² Includes food, clothing, household operating expenses, furniture and furnishing, and building material for house.

Bureau of Agricultural Economics, compiled from prices reported to the Department of Agriculture by retail dealers throughout the United States.

The index numbers include only commodities bought by farmers; the commodities being weighted according to purchases reported by actual farmers in farm management and rural-life studies from 1920 to 1925.

Bureau of Agricultural Economics: prices of farm production received by producers collected monthly from a list of about 12,000 special price reporters.

This list is made up almost entirely of country town dealers, elevator managers, buyers, and merchants. The commodities by groups are as follows: Grains—wheat, corn, oats, barley, rye, kafir; fruits and vegetables—apples, oranges, grapefruit, potatoes, sweetpotatoes, beans, onions, cabbage; meat animals—beef cattle, calves, hogs, sheep, lambs; dairy products—butter (represents butter, butterfat, and cream), milk; poultry products—chickens, eggs; cotton and cottonseed; all groups includes also horses (represents horses and mules), hay, flax, tobacco, and wool.

¹ Yearly averages are from reports by crop reporters, giving average wages for the year in their localities.

² This column has significance only as an essential step in computing the wage index.

³ Calendar years 1910-14=100.

⁴ Weighted average of quarterly reports, April (weight 1), July (weight 5), October (weight 5), and January of the following year (weight 1).

Bureau of Agricultural Economics.

United States.....																		

1 These data represent new estimates for individual States for the years prior to 1924 and a revision of previous estimates since that year. A more adequate sample, improved methods of calculation, and modified variable weights underlie the revision.

¹ This table is a supplement to table 475, pp. 737 to 739, Yearbook of Agriculture, 1933, and includes data from recent studies and other studies not available at the time of publication of the 1933 Yearbook.

² The numbers indicate the agency which obtained the data, and the letters indicate the method used in obtaining the data, as follows: 1, Bureau of Home Economics, U. S. Department of Agriculture, in cooperation with State Agricultural Experiment Station; 2, State university, agricultural college, or agricultural experiment station; 3, Bureau of Agricultural Economics, U. S. Department of Agriculture, in cooperation with State agricultural experiment station; S, schedule method of obtaining data; R, record or account-book method of obtaining data.

³ Includes expenditures for fuel, light, household supplies, and hired help; in some cases includes also those for laundry done outside, telephone, postage, express and freight, insurance on furniture, dry-cleaning and pressing, moving charges, interest on family debts, ice, and water.

⁴ Size of household.

⁵ Includes life insurance but no other savings.

⁶ Goods furnished by the farm evaluated at farm prices.

⁷ Evaluated at 10 percent of estimated value of house.

⁸ Automobile only.

⁹ Not included in this report.

¹⁰ Life insurance included with other savings.

¹¹ Includes health and accident insurance.

¹² Goods furnished by the farm evaluated at local prices.

¹³ Records from identical families for consecutive years.

¹⁴ Goods furnished by the farm evaluated at retail prices.

¹⁵ Size of family in adult-equivalent units.

¹⁶ Basis of valuation not given.

¹⁷ Estimated on basis of interest on investment and depreciation.

¹⁸ Automobile for family use included with household operation expenditures.

¹⁹ Figures on life insurance and other savings not yet available.

²⁰ Not given separately.

Bureau of Home Economics.

¹ Approximately equivalent to the food value of 1 quart of fluid whole milk: 17 ounces of evaporated milk; 1 quart of fluid skim milk and 1½ ounces of butter; 5 ounces of American Cheddar cheese; 4½ ounces of dried whole milk; 3½ ounces of dried skim milk and 1½ ounces of butter.

² For the adult woman this may be reduced to 182 quarts. For pregnant or nursing mother it should be increased to 365 quarts.

³ Including butter, oils, bacon, and salt pork.

⁴ 1 pint (1½ pounds) of molasses or heavy cane or sorgo sirup is approximately equivalent in fuel value to 1 pound of granulated sugar. The unrefined molasses and sirups are also valuable for their calcium and iron content.

¹ Based on yield shown in crop report of Dec. 8, 1933.

Agricultural Adjustment Administration.

Performance certificates received totaled 1,027,585. This represents a performance of 99 percent. Some performance certificates covered more than 1 contract.

TABLE 489.—*Summary of results ¹ of 1933 cigar-leaf tobacco (filler and binder types) acreage-adjustment program of the Agricultural Adjustment Administration, by districts and by States*

[Approximate totals, Feb. 10, 1934]

District	Extent of sign-up			Base acreage planted to tobacco			Acreage retired after planting

¹ Official estimates of the Bureau of Agricultural Economics, December 1933.² Some counties and individuals in numerous counties used 4-year and 5-year bases, which are included in this figure.³ Applicants' production adjusted to a 5-year base.⁴ Estimated payments at 28 cents per bushel on 54 percent of the base production.⁵ Acreage in excess of official estimates allowed. Percentage of sign-up computed from the total acreage allowed.⁶ Estimated figures, as reports from some counties not received at time of this tabulation.

Agricultural Adjustment Administration.

TABLE 491.—Marketing agreements entered into during 1933 through the Special Crops Section of the Agricultural Adjustment Administration

[All data subject to minor revision]

Commodity and State	Effective date in 1933	Unit	Volume included under agreement	United States production, 1933 season	Percentage under agreement
Cling peaches canned in California	Aug. 17	Cases	¹ 10,000,000	10,000,000	100
California fresh deciduous tree fruits, except apples, ²	Sept. 2	Cars	³ 13,175	120,332	52
Northwestern ⁴ fresh deciduous tree fruits.	Oct. 14	do	⁵ 49,366		
California Flame Tokay grapes	Sept. 30	do	4,032	⁷ 43,900	(6)
Walnuts grown in California, Oregon, and Washington.	Oct. 9	Tons	43,900		
California ripe olives used for canning	Dec. 13	do	12,000	12,000	100
Oranges, grapefruit, and tangerines:					
California and Arizona	Dec. 14	Boxes	27,508,000		
Florida	do	do	22,866,000		
Texas	Dec. 26	do	1,638,000		
Total (including mixed citrus)		do	⁸ 52,012,000	52,180,000	99.7
Canning tomatoes ⁹	August	Tons	993,400	993,400	100
Canning corn ⁹	do	do	393,000	393,000	100
Canning lima beans ⁹	do	do	8,800	8,800	100
Canning beets ⁹	September	do	24,800	24,800	100
Cabbage for sauerkraut ⁹	do	do	95,400	95,400	100

¹ Basis of 24 No. 2½ cans. Actual pack exceeded this slightly; the exact amount not yet determined.² Agreement not consummated early enough to be operative for 1933 apple crop.³ Includes apricots, cherries, peaches, pears, plums, and fresh prunes for 1933.⁴ Washington, Oregon, Idaho, and Montana.⁵ Total of cherries, peaches, pears, plums, and fresh prunes shipped in 1933 and apples in 1932-33.⁶ Represents 25 percent of table grapes shipped from California; United States table grapes not listed separately.⁷ Total 1933 production, plus some carry-over.⁸ Average boxes per carload: California and Arizona, 462; Florida and Texas, 360. (Florida and Texas include movement by truck.) Crop year 1932-33.⁹ At the request of the Agricultural Adjustment Administration, the canning industry agreed to voluntary price increases to growers. No licenses issued.

Agricultural Adjustment Administration; compiled from records of the Special Crops Section and reports of the Bureau of Agricultural Economics.

* Station closed June 30, 1933.

† Normals are based on records of 20 or more years of observations.

Weather Bureau.

T=Trace, indicates an amount too small to measure.

TABLE 494.—Frost: Dates of killing frosts, with length of growing season

Station	Date of last killing frost in spring, 1933	Date of first killing frost in fall, 1933	Averages and extremes of killing frost for 30 to 51 years				Length of growing season between average dates of killing frosts
			Spring frosts		Fall frosts

3	Southwestern region.....	Albuquerque, N. Mex.....	22,001,759	2,105,700	19,896,059
4	Intermountain region.....	Ogden, Utah.....	30,532,477	1,346,768	29,185,709
5	California region.....	San Francisco, Calif.....	24,212,897	4,862,686	19,350,211
6	North Pacific region.....	Portland, Oreg.....	26,923,992	3,827,898	23,096,094
7	Eastern region.....	Washington, D. C.....	10,405,444	5,201,239	5,204,205
8	Alaska region.....	Juneau, Alaska.....	21,396,951	54,477	21,342,474
9	North Central region.....	Milwaukee, Wis.....	3,795,575	1,823,313	1,972,262
	Total.....		186,837,499	24,828,354	162,009,145

Headquarters of national-forest areas:

Region 1, Federal Building, Missoula, Mont.; embracing Montana, northeastern Washington, northern Idaho, and northwestern South Dakota.

Region 2, Federal Building, Denver, Colo.; embracing Colorado, eastern Wyoming, South Dakota, Nebraska, and western Oklahoma.

Region 3, Gas and Electric Building, Albuquerque, N. Mex.; embracing Arizona and New Mexico.

Region 4, Forest Service Building, Ogden, Utah; embracing Utah, southern Idaho, western Wyoming, Nevada, and northwestern Arizona.

Region 5, Ferry Building, San Francisco, Calif.; embracing California and southwestern Nevada.

Region 6, Post Office Building, Portland, Oreg.; embracing Washington and Oregon.

Region 7, Victor Building, Washington, D. C.; embracing Alabama, Arkansas, Florida, Georgia, Louisiana, Maine, New Hampshire, North Carolina, Pennsylvania, Puerto Rico, South Carolina, Tennessee, Vermont, Virginia, and West Virginia.

Region 8, Federal Building, Juneau, Alaska; located in Alaska.

Region 9, Federal Building, Milwaukee, Wis.; embracing Illinois, Michigan, Minnesota, and Wisconsin.

Forest Service.

See 1931 Yearbook, table 554, p. 1041, for lists of National Monuments, National Game Refuges, and Range Reserves.

TABLE 499.—*Saw-timber area, stand, growth, and depletion in the United States*

Total.....	188,645	1,667,803	11,731	54,642	1,390	3,402	59,434

¹ Standing timber of all species of size suitable for lumber according to the local practice in each region, as of 1930.

² Current annual growth of timber of saw-timber size.

³ Cut for lumber and other commodities, averaged for the period 1925-29.

⁴ Saw timber destroyed, averaged for the period 1925-29.

⁵ Destruction due to insects, disease, windfall, etc., averaged for the period 1919-29.

⁶ Includes New York, Pennsylvania, New Jersey, Delaware, and Maryland.

⁷ Includes Ohio, Indiana, Illinois, Iowa, Kansas, Missouri, Nebraska, Tennessee, Kentucky, and West Virginia.

⁸ Includes the coastwise States, Virginia to Texas, inclusive; also Arkansas and Oklahoma.

⁹ Includes Idaho and Montana.

¹⁰ Includes the other Rocky Mountain States and South Dakota (Black Hills).

Forest Service; from a National Plan for American Forestry, 1933.

Wyoming.....									

¹ Northern white pine in States east of the Great Plains. Western white pine in Idaho, Montana, and Washington. Sugar pine in Oregon and California.

² Includes all sales of southern pines.

³ Balsam fir in Eastern States. White fir in Western States.

⁴ Red, black, and white spruce in Eastern States; Sitka spruce in California, Oregon, and Washington; Engelmann spruce in Colorado, Utah, and Wyoming.

⁵ Eastern and western hemlock for Eastern and Western States, respectively.

⁶ Northern white cedar in Maine and Michigan; Port Orford cedar in Oregon; eastern red cedar in Alabama; and North Carolina; western red in other States.

[illegible]

¹ Initial Federal-aid construction refers to projects which are being improved with Federal aid for the first time. Such projects may or may not have been previously improved.

² The term "stage construction" refers to additional work done on projects previously improved with Federal aid. In general, such additional work consists of the construction of a surface of higher type than was provided in the initial improvement.

Bureau of Public Roads.

TABLE 516.—Mileage of roads in State highway systems, including Federal-aid system, at end of 1932, and total mileage 1921, 1923-31, as reported by State highway departments

State and year	Total system mileage	Earth non-surfaced		Surfaced roads by types							
		Unimproved	Improved to grade	Total surfaced mileage	Sand-clay, top-soil	Gravel, chert, etc.	Water-bound macadam (treated and untreated)	Bituminous macadam	Bituminous concrete	Portland cement concrete	Brick and block

1933 ¹	35	34	38	29	21	19	28	47	48	32

¹ Does not include wage rates on public works highway projects. For these projects it is required that minimum wage rates, sufficient to provide, for the hours of labor as limited, a standard of living in decency and comfort. Shall be fixed by State highway departments. The averages of these rates for common labor were as follows: New England 40 cents, Middle Atlantic 40 cents, East North Central 47 cents, West North Central 45 cents, South Atlantic 31 cents, East South Central 30 cents, West South Central 35 cents, Mountain 55 cents, Pacific 56 cents, and United States 44 cents.

TABLE 522.—*Fertilizer materials: Sales and production of agricultural lime, phosphate rock, sulphur, and pyrites, in quantity and value, United States, 1930-32*

Item	Quantity			Value		
	1930	1931	1932	1930	1931	1932
Agricultural lime and liming materials sold: ¹						
Lime from limestone:	<i>Short tons</i>	<i>Short tons</i>	<i>Short tons</i>	<i>Dollars</i>	<i>Dollars</i>	<i>Dollars</i>
Quicklime	91,521	78,392	220,000	512,383	422,107	
Hydrated	251,590	218,920		1,860,396	1,502,042	
Lime from oyster shells ²	15,000	11,207		135,000	85,834	
Limestone pulverized	2,542,100	1,421,050		3,309,329	2,117,141	
Calcareous marl	34,012	25,056		112,523	65,935	
Total	2,934,223	1,754,625		5,929,631	4,103,109	
Phosphate rock sold or used: ³						
Sold for direct application to the soil	<i>Long tons</i>	<i>Long tons</i>	<i>Long tons</i>			
Florida:						
Hard rock	81,753	57,224	57,579	517,229	390,540	373,251
Land pebble ⁴	3,166,318	2,004,242	1,412,397	10,273,076	6,821,546	4,406,361
Tennessee:						
Brown and blue rock	611,045	343,622	193,666	2,938,525	1,545,607	776,367
Other States ⁷	67,276	129,871	43,262	268,000	540,792	182,514
Total	3,926,392	2,534,959	1,706,904	13,996,830	9,288,485	5,738,493
Sulphur produced	2,588,981	2,128,930	890,440			
Sulphur sold	1,989,917	1,376,526	1,108,852	35,800,000	24,800,000	20,000,000
Pyrites produced	347,512	330,848	186,485	1,028,630	974,820	492,043

¹ Sold by producers. (Includes a small amount sold by Hawaii and Puerto Rico producers.)

² Partly estimated.

³ Sold or used by producers.

⁴ Includes soft rock.

⁵ Includes a small quantity of tailings.

⁶ Includes a small quantity of apatite from Virginia.

⁷ Idaho, Wyoming, and Montana.

Bureau of Agricultural Economics; compiled from reports of the Bureau of Mines. Figures for earlier years appear in previous issues of the Yearbook.

¹ Except as follows: New Hampshire, Massachusetts, Idaho, and Oklahoma (1922-28), year ended June 30; Rhode Island, year ended Mar. 31; New Jersey, year ended Oct 31.

² Preliminary.

³ Estimated by State authorities.

⁴ Estimated.

⁵ Agricultural census.

⁶ Based on tag sales.

⁷ Total of 4 companies plus estimates for others.

Bureau of Agricultural Economics; compiled from reports of the National Fertilizer Association, published in the Fertilizer Review; based on fertilizer tag sales or sale records, or estimates, as shown in footnotes.

TABLE 524.—*Fertilizer and fertilizer materials: Production, sales, imports, exports, and consumption, United States, 1928-32*

¹ Preliminary.² Byproduct of coke ovens; production from other sources (coal, gas, bone carbonizing, etc.) is usually less than 5 percent of the total production.³ Includes ammonia liquor NH_3 content converted to sulphate equivalent.⁴ Fertilizer establishments only.⁵ Bulk superphosphate. Superphosphate in base and mixed goods excluded.⁶ Includes kainit, manure salts, sulphate of and muriate of potash.⁷ Originated mostly in Germany.⁸ Originated mostly in France.

Bureau of Agricultural Economics; compiled as follows: Production and sales, sulphate of ammonia and potash from Bureau of Mines; sulphuric acid and superphosphate from Bureau of the Census; imports and exports from Bureau of Foreign and Domestic Commerce.

TABLE 525.—*Nitrogen: World production of, contained in inorganic nitrogenous materials, 1929-33*

Total.....	2,324,300	2,423,800	1,863,700	1,743,700	1,831,600

¹ Including ammonia products used for industrial purposes and ammonia in mixed fertilizers.

Bureau of Chemistry and Soils; British Sulphate of Ammonia Federation Ltd., annual report.

Fertilizers are included in this table under the final form as sold, so that, for example, cyanamide if converted into sulphate of ammonia is included under synthetic sulphate of ammonia, or, if into ammonophos, is included under other synthetic nitrogen.

Exports.....		2,252,644	1,258,139		

¹ Byproduct from the mining of copper, lead, and iron ores. (Bureau of Mines.) The Census of Manufactures gives production for 1929 as 42,926,400 pounds and 1931 as 43,704,148 pounds.

² Sales by producers. (Bureau of Mines.)

³ Copper industry only. (Bureau of Mines.) The total production as reported by the census for 1929 was 78,669,112 pounds; and 1931, 60,981,335 pounds.

⁴ Nicotine sulphate and "other tobacco extracts."

⁵ Classified as sheep dip.

Bureau of Agricultural Economics; production and sales from Bureau of the Census and Bureau of Mines (indicated by footnote); imports and exports from the Bureau of Foreign and Domestic Commerce.

¹ Weight as delivered at original shipping point. In the case of freight transported over several different railways, each ton is counted only when transported by the first railway. Some traffic, reshipped under new billing without benefit of transit privileges or proportional rates, may be counted more than once.

² Preliminary.

Bureau of Agricultural Economics, compiled from reports of the Interstate Commerce Commission. Figures for earlier years appear in previous issues of the Yearbook.

1933 ⁵	70, 361	1. 534	207, 500	6, 157	. 609	. 503

¹ Net imports are imports minus reexports.

² Average of monthly average prices of Japanese Kansai, No. 1.

³ Net imports are imports minus reexports 1924. Subsequent years are imports minus exports and reexports.

⁴ Average of monthly average prices. The count indicates the number of deniers or one half decigram units, in weight, of a standard length of 450 meters. Since the standard is based on an arbitrary fixed length and a variable weight, the finer the yarn the smaller the count; 150 denier count, a size commonly used, is fine and 300 denier count is coarse.

⁵ Average of monthly average prices of Japanese Best, No. 1 x 13-15.

⁶ Preliminary.

Bureau of Agricultural Economics; compiled from annual issues of Commerce and Navigation of United States Department of Commerce, except production of rayon yarn which is from Yearbook of the Department of Commerce; prices are from bulletins of the U. S. Bureau of Labor Statistics.

Income—	
farm—	
commodities, 1933.....	55-61
families, from sources other than farm business, data.....	720
relation to factory pay rolls.....	107-108
gross, from farm products, 1930-32.....	695-698
Incomes, farmers', contribution of truck crops to.....	358
Index—	
numbers—	
agricultural exports, 1909-33.....	662
farm prices, 1910-33.....	706-708
farm real estate, 1912-33.....	710
farm wages and rates, 1903-33.....	709
freight rates, 1913-32.....	762
prices paid by farmers, 1910-33.....	706
volume of agricultural production, 1919-33.....	693
truck crops, inclusion of 13 products. Arthur G. Peterson.....	358-360
Industrial codes, effect on farm prices, discussion by Secretary.....	13-15
Information Service, Department, cooperation under A. A. A.....	67-68
Insect pests, survey and control work.....	84-89
Insecticides—	
imports and exports, 1928-32.....	754
prices at New York, 1924-33.....	754
production and sales, 1928-32.....	754
use on fruits and vegetables, recommendation.....	88-89, 96
See also Fungicides.	
Insulation material, uses of eelgrass.....	191-192
Interior, Department of the—	
aid in purchase of subsistence homesteads.....	24-25
cooperation in Emergency Conservation Work program.....	197-198
Irrigation—	
studies, discussion by Secretary.....	83
weeds and noncrop plants, costly and unprofitable results. O. V. P. Stouts.....	250-253

KENDRICK, J. F.: Dairy Sires Proved at Earlier Age by Lactation Records.....	184-185
KIRCHER, JOSEPH C.: Green Mountain National Forest to Aid Development of Forestry in Vermont.....	241-242
KNOX, C. W.: Poultry Meat Production Costs Reduced by Cross-Breeding and Good Diets. With H. W. Titus.....	296-298
KREUGER, THEODORE: Forests Helped by Thinnings Made under "Free Use" Provision.....	227-229
Labor, farm, wages, by geographical divisions, 1933.....	709
Labor, Department of, cooperation in Emergency Conservation Work program.....	197-198
Lactation—	
records, use in proving of sires at earlier age by comparison of milk production of daughters and dams. J. F. Kendrick.....	184-185
stimulation by pituitary hormone.....	360-362
Lactobacillus spp., importance in making Swiss cheese.....	340-342
Lake States—	
timber lands, fire-control roads and motorway fire lines. H. Coleman.....	216-217
tree-nursery development to meet new planting program. H. Basil Wales.....	355-357
Lamb—	
prices, 1929-33.....	121-122
trade, international, 1925-32.....	614
See also Meat; Meats; Mutton; Sheep.	
Lambs—	
number on farms, and value, 1900-1934.....	606, 609
prices—	
farm, 1924-34.....	610
market, 1924-33.....	611
shipments and slaughter, 1932.....	612-613
slaughter under Federal inspection, 1900-1933.....	611
Land—	
classification, use of soil surveys as basis. C. F. Marbut.....	327-329
idle, new uses for.....	93
prices in East and South as shown by Government purchases. P. J. Paxton.....	253-255
terracing for erosion control. Chas. E. Ramser.....	346-348
use planning, Federal and State cooperation.....	23-25
Lard—	
exports—	
1909-33.....	663
destination, 1926-33.....	669
prices, 1924-33.....	602-603
